ON THE USE OF GALVANISM IN CHRONIC DISEASES OF THE PHARYNX.*

BY E. L. SHURLY, M. D.,
DETROIT.

YOU will doubtless remember that at the Congress of 1880 I presented a short paper calling attention to the use of galvanism in the treatment of pharyngitis sicca. At that time I had had but a limited experience with this agent in such conditions, but since then I have used galvanism in a number of cases with, I think, such good results as to justify me in again calling your attention to the subject. The difficulties which I then narrated as attending the use of electrodes in the pharynx can be much reduced through the use of cocaine, and therefore this treatment is practicable for almost any person. I believe it is very generally confessed that our knowledge of the pathology and pathogenesis of the chronic affections of the pharyngeal mucous membrane is far from exact or complete.

Certain well-recognized features or symptoms, such as habitual engorgement, hypersecretion, glandular enlargement with or without paucity or perversion of secretion, constituting the local manifestations of many cases which present themselves to us, and which, I am sorry to say, puzzle us in the selection of the proper means for amelioration. That some of these conditions of the pharynx—chronic engorgement, hypersecretion, etc.—are often only local expressions of a derangement of the stomach, the intestinal canal, or possibly some more remote organ, is well known and does not surprise us, since the anatomical and physiological connection or relationship between these organs and the pharynx is probably intimate. We also meet with neuroses of the pharynx—hyperæsthesia, spasm, paræsthesia, etc.—which are dependent upon derangement either of these same organs or the genito-urinary or mental apparatus, all of which require little or no local treatment. But, besides this class of cases, there are certain organic lesions of the pharyngeal mucous membrane which can not be traced to any particular disorder of the neighboring or remote organs or glands, which are characterized by changes such as glandular hypertrophy, general hyperplasia, hypersecretion with or without extraordinary epithelial development, atrophy with diminished secretion, etc. It is to these that I wish particularly to call your attention.

They constitute changes which may be regarded as trophic, and which, however inexplicable, must be regarded as distinct local disorders. In my mind there has long been a conviction that glandular hypertrophy and atrophy with or without persistent extra secretion and without much organic change in the membrane are due to a perversion of function of the nervous apparatus distributed to the pharyngeal region. It does seem impossible that the mere mechanical effect of infiltration or interstitial deposit can account altogether for the wasting of the membrane. Likewise does it seem impossible that the disagreeable symptoms of typical pharyngeal disease, even when associated with thickening or wasting of the glandulæ, etc., can be fairly attributed to ordinary inflammation and its consequences, because we often find people with throats presenting such appearances, even to a considerable degree, who do not complain of inconvenience nor show disturbance of the nutrition of the part. Therefore it would seem probable that some of these conditions must be at least regarded as distinct local disease having for its origin some nutritive abnormality antecedent to the inflammatory changes; and may we not find a possible explanation in the supposition of metabolic derangement through a disordered trophic function of the hypoglossal, pneumogastric, or sympathetic nerves?

Considering the analogy between the functions of the hypoglossal and the fifth, and the facts already demonstrated regarding the trophic influence of the latter nerve, this hypothesis would seem to gain support. However, the light of further investigation may show that, instead of the hypoglossal, either the pneumogastric or sympathetic, or both, may be the reigning influence in the nutritive changes of the pharyngeal mucous membrane; but, whichever may be the case, the result is the same. Acting upon the foregoing theory, I have been led into the employment of different agents for local use, with a view of counteracting this perverted trophic influence; but, of all the agents used, I think I have obtained more lasting effects from galvanism. Many of the local stimulant applications, while certainly valuable, are soon followed by a reaction which shows the excitement to have been only of short duration and in no wise of vital character. But with the galvanic current I think I have found much more enduring effects; for example, the mucous membrane remains in many cases of a vivid color and bathed in a quite fluid secretion for a number of hours after the application, and, moreover, leaves a sensation of heat and pliability—in cases of atrophy—which the patients describe as slightly exhilarating. The effect of the application is sometimes felt in adjacent parts—such as the cervical region. One of my patients states that the sensation of heat always remains in his throat for about forty-eight hours. After a few applications the sense of dryness and the collection of desiccated secretion in and about the naso-pharynx, which occur in the severer forms of chronic naso-pharyngeal disease, very sensibly lessen. In cases of engorgement accompanied by hypersecretion the result of this treatment has been quite efficient. Also in distinctly neurotic conditions—such as paræsthesia—I have had good effects from galvanism.

I usually pursue the following method, viz.: First wash off the surface of the membrane, by means of a spray or posterior douche, with a solution of common salt or other appropriate fluid; then apply a four-per-cent. solution of cocaine hydrochlorate, and, after an interval of about five minutes, apply the electrodes (which I here show you), one through the nasal passage and the other to the posterior and lateral wall of the pharynx, moving them both rapidly but gently over the surface, being careful to keep them

* Read before the American Laryngological Association, June 24, 1885.

closely applied. I generally connect the electrodes with two cells (increasing to four or five) of a battery composed of the improved Leclanché cells. The electrodes are not covered, but naked, unless it is desired—as in cases purely nervous—to apply one electrode to the side of the neck, when that is covered. Gagging and muscular movements require the removal of the instruments, after a few seconds, for a short period of repose, when they are reapplied perhaps four or five times, according to the tolerance of the patient and the sensible effect produced. The *séance* may be repeated two or three times a week, as may seem advisable. I have experienced the greatest difficulty from the intolerance of the parts in question to the manipulation, but, as before mentioned, the use of cocaine has afforded, in the majority of cases, the desired tolerance. However, as might be expected, the drug to a certain extent antagonizes the effect of the galvanic application, and must be compensated for either by a longer or more frequent manipulation. In some cases one thorough treatment a week will prove sufficient.

Of course, it is not expected that this, any more than any other, plan of treatment will restore already destroyed tissue, but that it is competent to arrest those metamorphoses which finally result in either the loss of glandular as well as other elements of the membrane, or the substitution of adventitious for the normal tissues, I firmly believe, in view of my experience with it. The period of time required for reaching permanent results will vary, of course, according to the kind of case and the state of chronicity presented. The only therapeutic theory which I have to offer is a very commonplace one, viz., the restoration of the nutrition and normal secretion of the parts through the direct application of the electric fluid to the terminal nerve-filaments.

THE RESPIRATORY FUNCTION OF THE HUMAN LARYNX.*

FROM EXPERIMENTAL STUDIES IN THE PHYSIOLOGICAL LABORATORY OF HARVARD UNIVERSITY.

By FRANKLIN H. HOOPER, M. D.,
BOSTON.

The human larynx has two principal functions: (*a*) The respiratory, (*b*) the phonatory. They are mentioned in the order of their importance, for, while the muscles concerned in phonation, supplemented by other constrictors, are charged with the additional duty of closing the laryngeal aperture to protect the air-passages from the entrance of foreign bodies, yet it must be conceded that, whether employed in phonation — marvelous as this function is—or brought into action to exclude some foreign substance, the part performed by these constrictors is entirely subordinate to that of the respiratory muscle of the larynx, whose office is to hold the glottis open in order to insure an uninterrupted passage of air to and from the lungs.† Nevertheless, it is this important muscle which is not only the chief among the intrinsic muscles of the larynx, but also one of the most essential of the whole body—a muscle, be it remembered, of *organic life* *—that many writers would have us believe has a special tendency to succumb to disease. Gerhardt, in his well-known paper,† was perhaps the first to speak of unilateral paralysis of this muscle (the posterior crico-arytenoid) as the most innocent of all forms of laryngeal paralyses. He points out that neither the voice nor the respiration is impaired in such lesions. Schech‡ writes in the same strain, and believes that, as the voice and quiet respiration are not affected in these instances, this circumstance accounts for their having escaped more frequent mention. Two prominent exponents of this theory (Rosenbach # and Semon ‖) have stated that in central or peripheral affections where the filaments of the recurrent laryngeal nerve are compressed, the fibers innervating the respiratory muscle are earlier affected than those going to the phonatory muscles; that this is in accordance with the well-ascertained fact that, in central or peripheral nerve lesions, the extensor muscles △ are more readily paralyzed than the flexors; that there is a "proclivity of the *ab*ductor fibers of the recurrent laryngeal nerve to become affected sooner than the *ad*ductor fibers, or even exclusively, in cases of undoubted central or peripheral injury, or disease of the roots or trunks of the pneumogastric, spinal accessory, or recurrent nerves." Another author ◊ has recently gone so far as to say that the vulnerability of these *ab*ductor fibers is a fact upon which all observers are now agreed.

We hazard the opinion, notwithstanding, that if we investigate this complicated subject from a somewhat different point of view—one not strictly clinical—we may discover certain reasons why one should not subscribe unconditionally to this conception of the pathology of laryngeal neuroses. We propose, therefore, to inquire into the truth of this problem purely from an anatomical, physiological,

---

* Read before the American Laryngological Association, June 24, 1885.

† The intrinsic laryngeal muscles are in pairs except one, the transverse arytenoid. The posterior crico-arytenoids are the respiratory muscles. The phonatory muscles, which, like the respiratory muscles, are attached to the arytenoid cartilages, are the internal thyro-arytenoids, the lateral crico-arytenoids, and the transverse arytenoid. These phonatory muscles are, when it is necessary, brought into action solely to close the glottis and not for the purpose of phonation. Under these circumstances they are supplemented by the muscles which compose the aryteno-epiglottidean folds, and which, together with certain other muscular fasciculi, may be classed as the sphincter group—the constrictor vestibuli laryngis. The thyro-cricoids are also phonatory muscles; but with these, on account of their anatomical situation, we have nothing to do in this paper.

* By this expression we refer to the normal automatic character of the muscular action, and not to the microscopic structure of the muscle itself.

△ To this assumption that the posterior crico-arytenoid muscles are *extensors* we shall recur.

◊ Gottstein, "Die Krankheiten des Kehlkopfes," p. 192, Wien, 1884.

and experimental standpoint. This being, then, in no sense, a clinical paper, clinical evidence will not be offered, although the writer's experience is far from being in accord with the dictum that the nerve filaments which preside over the most useful and important function of the larynx should be especially prone to have that function arrested. The superior laryngeal nerve, and the median laryngeal, recently described by Exner,* need not in this study concern us. The only other nerve, as far as we know to-day, going to the intrinsic muscles of the larynx is the inferior or recurrent laryngeal. This nerve, according to our present knowledge, is purely motor, † and supplies all the intrinsic laryngeal muscles except the longitudinal tensors, the thyrocricoids. It is an anatomical fact that it does not send off any branches to these muscles until it has reached the border of the cricoid cartilage. In its trunk, therefore, are contained two sets of nerve fibers—the respiratory and the phonatory—which must necessarily be strictly differentiated, since they are destined for muscles which carry on two separate and distinct functions. Now, where do these two sets of nerve filaments come from; is their origin as distinct as their function; whence do they derive their separate individualities; which are relatively or numerically the stronger?

The sources from which nervous impulses for the larynx may be received are the brain, the medulla oblongata, and the spinal cord. The channels through which they may be transmitted are the several motor nerves which join the pneumogastric before the recurrent is given off, for we are aware that from this point the recurrent proceeds to the larynx without any branch or junction which is in any way connected with the functions of that organ.

The experimental researches of Krause,‡ and the clinical observations of Delavan,# justify the belief that there is a center of motion for the larynx in the cortical substance of the brain. It is also probable, as advanced by many, that the several nerve filaments of the recurrent laryngeal may have independent ganglionic centers somewhere in the brain or medulla. Let us now follow down the real motor nerve tract of the larynx from the medulla oblongata to the point of exit of the recurrent laryngeal from the pneumogastric, and enumerate the different nerves which, from what we know positively or imagine hypothetically, may in any way influence either of the functions of the larynx. In so doing we shall adopt Longet's classification,‖ who divided them into the *direct* and the *indirect*. Starting, then, at the medulla, we name as the direct communications to the pneumogastric the internal branch of the spinal accessory, the facial, the hypoglossal, and the anterior branches of the first and second cervical. The sympathetic may also furnish some direct fibers. Under the head of indirect nerves—namely, those which join the pneumogastric after having previously passed through the sympathetic ganglia—we have all the branches of the cervical below the second, and those of the dorsal nerves situated, of course, above the point where the inferior laryngeal shoots off from the pneumogastric to run its backward course to the laryngeal muscles.

Our knowledge of the part played by these different nerves in the performance of the functions of the larynx is now, and, from the inherent difficulties of the problem, must for a long time to come remain, unsatisfactory. The mass of contradictory statements which one encounters in working up a subject in any way connected with the respiration, and consequently with the pneumogastric nerve, is a sufficient admonition against too positive and dogmatic assertions. We approach this question, therefore, with reserve, admitting, as we must, that a great part of the subject is yet hardly beyond the confines of plausible conjecture.

It is pretty certain, however, as determined by the reliable experiments of Bischoff,* Longet,† Cl. Bernard,‡ and Schech (*loc. cit.*), that the spinal accessory is a purely motor nerve presiding over phonation, and having nothing to do with the respiratory function of the larynx.# That there may be other phonatory fibers in the pneumogastric we can not gainsay. Now, how is the respiratory function innervated? Probably in many different and complex ways, in accordance with the truth of the physiological law enunciated by Longet.‖ "Les moyens d'innervation propres à entretenir le jeu d'un organe se multiplient en raison de son importance physiologique." The posterior crico-arytenoids—the respiratory muscles of the larynx—are paramount to all the rest in physiological importance. From many sources they re-

* "Die Innervation des Kehlkopfes," "Sitzungsb. d. k. Akademie d. Wissenschaften," Band 89, Abth. iii, 1 u. 2 Heft, 1884.

† We are aware that some have stated, but without giving experimental data to substantiate the assertion, that the recurrent contains sensory as well as motor fibers. We have not the space here to dwell upon our own experiments to determine this point, but they justify our remark that the recurrent is "purely motor."

Experimental physiology teaches us that if we cut the recurrent nerves of a kitten or a puppy a few days old it immediately dies of suffocation, which is not the case in old animals. The reason of this, as originally explained by Legallois ("Expériences sur le principe de la vie," Paris, 1812), is because in very young animals the cartilaginous portion of the glottis is but slightly developed, and, the soft and yielding parts not being held in position by the muscles, the laryngeal walls are sucked together by the inspiratory effort, and the laryngeal aperture is accordingly completely closed. Cl. Bernard showed that section of the spinal accessory in a kitten five weeks old was followed by aphonia, but glottic respiration remained free. Two days afterward, the kitten having remained well but voiceless, its recurrents were cut, when it instantly died asphyxiated. He concludes from this that the pneumogastric has a motor power independent of the spinal accessory which permits the animal to breathe after the latter has been cut; or, in other words, the larynx is a vocal organ when excited by the spinal accessory, and a respiratory organ when under the influence of the pneumogastric, or more probably of other motor nerves associated with it. In certain animals, as the chimpanzee, the internal branch of the spinal accessory does not blend with the pneumogastric, but goes direct as a separate nerve to the larynx.

‖ "Traité de phys.," vol. iii, p. 517, Paris, 1869.

ceive an abundant nerve supply, which is to protect them from disease, not to open up new channels by which harm might come to them. With others we assume that there are independent ganglia in the central nervous system which are essentially their own. Being respiratory muscles, it is more than probable that they may receive nerve force from such respiratory nerves as the facial, the hypoglossal, and the others already mentioned which run into the pneumogastric. But in this connection we must quote Longet's own words:* "Si la phonation, fonction secondaire et accessoire, dépend d'un nerf unique et disparaît avec lui, la dilatation respiratoire de la glotte, si essentielle, si indispensable à la conservation de la vie, est sous la dépendance ou plutôt sous la protection de nerfs multiples qui, dans certains limites, peuvent se suppléer les uns les autres. Aussi, comme je l'ai déjà fait remarquer, précisément avant de donner origine aux récurrents qui animent les muscles crico-aryténoïdiens postérieurs, voit-on les pneumogastriques emprunter des fibres motrices à des nerfs qui tous interviennent dans la respiration."

Summing up what has preceded, we can say that it all points to the conclusion that the respiratory nerve filaments contained in the recurrent laryngeal are derived from a greater variety of sources than the phonatory.

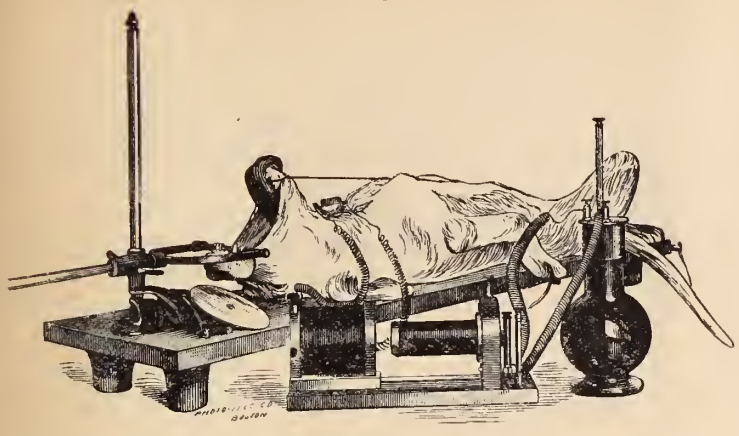
We pass now to the experimental evidence bearing on this point. It is a fact, familiar to all, that if anything other than air finds its way into the larynx it produces, by reflex action, a sudden closure of the glottis. It is equally certain that, under normal conditions, the same contraction of the laryngeal muscles may be instantly called forth by direct stimulation of one or both of the recurrent nerves. Now, it may with reason be asked, How is it that this constricting action of the phonatory muscles is brought about if it be true that the nerve fibers animating the dilators of the glottis are the stronger and the more numerous? Why should we not get *ab*duction of the vocal bands instead of *ad*duction on irritating the recurrent nerves? The phonatory muscles are to the respiratory muscles as five to two, and the closure of the glottis has always been ascribed to the superior numerical strength of these constrictors. Yet if we compare, bulk for bulk, the muscular fibers which compose the five muscles of phonation with those of the two respiratory muscles, we do not find that they are much, if any, in excess of the latter, and we venture to think that there is some other factor concerned in this phenomenon apart from mere muscular force. It may be sought, perhaps, in this important difference between the respiratory and the phonatory function of the glottis—namely, that, while the respiratory muscles are ever on the alert, holding the glottis open during the entire healthy life of an individual, in his waking as well as in his sleeping hours, the phonatory muscles, on the other hand, are more dependent upon the *consciousness* of the individual in order to respond to any irritation. To explain: The phonatory function of the phonatory muscles could, as far as life is concerned, be dispensed with. Not so their constricting action with the view of excluding the passage of foreign bodies to the lungs. The constrictor muscles of the larynx are the sentinels who guard the approach to these vital organs. But they cease to act if the animal is in profound narcosis; they are asleep, so to speak, on their watch. A man in the condition known as "dead drunk," lying, let us suppose, on his back with his mouth open, would offer no obstacle to prevent any living insect that chanced his way from crawling in and out of his mouth, or meandering round in his larynx *à volonté*, without exciting reflex contraction of its muscles. The power of ether, chloroform, and other anæsthetics to impair the action of these constrictors is too well known to need mention. To carry this line of thought a little further, should we not expect that, provided we could preserve the organic life of an animal while its volition was at the same time completely abolished—should we not expect, we ask, under these circumstances, to get a dilatation of the glottis on irritating the recurrent nerves instead of a closure, for the posterior crico-arytenoid muscles are muscles of organic life? Indeed we believe we should, and we submit the following experiments in support of that belief. In performing the experiments the writer has had the advantage of the collaboration of Professor Henry P. Bowditch, to whom he would express his thanks. With one exception, when a horse was the subject of an experiment, the animals used were dogs, the proper selection of which for studies in experimental laryngology is highly important. If a dog is either very old or very large he is most unsatisfactory, if not absolutely worthless. He should be small and young; the breed is of no consequence. By arranging him in the following manner a perfect view of the glottis can be obtained: After being thoroughly etherized, he is secured on his back to a dog-holder. A longitudinal incision is made in the skin covering the larynx, the fascia is divided, and the muscles are drawn aside. The larynx and trachea are thereby brought into view. One or both of the recurrent laryngeal nerves may now be exposed. The mouth is held open by the upper jaw being firmly attached to the cross-bar of the dog-holder, while a cord, tied round the lower jaw and secured to any fixed point, keeps the jaws separated to the extent desired. If the animal is placed before a window, the light is transmitted through the wall of the trachea, illuminating the glottis below, while the ordinary head reflector throws the light in through the open mouth from above. The tongue may be stretched up over the lower jaw and secured to the skin by a thread. The epiglottis may be either tied up by a string passed through its tip, or held up by an instrument suitably curved, having a long handle. The accompanying picture, taken from a photograph of a dog in readiness for experimentation, may serve to make our description somewhat clearer. The animal is here shown under conditions by which both recurrents could be stimulated simultaneously.*

The phenomenon of an irritation applied to the recurrent laryngeal nerve producing an *ab*duction of the corresponding vocal band was first observed by accident. A

* *Loc. cit.*, p. 518.

* For the sake of completeness of the figure, the primary coil is represented as connected with a small bichromate cell, but in practice it was connected with a Grove cell in a battery-closet. The induction apparatus is the one described and figured in the "Proceedings of the American Academy of Arts and Sciences," October 12, 1875.

small dog, of no particular breed, of an age estimated at about ten months, as it still had some of its puppy teeth, was being prepared for a different order of research. On



looking for the left recurrent nerve, it was not found in its proper anatomical situation, but two small nerves were discovered near by. As it was doubtful what these two branches were, or whether they went to the larynx at all, a shielded electrode was placed on the outer and larger nerve, and, while the vocal bands were watched through the mouth, it was irritated. The very unexpected result of the stimulation was a forcible *ab*duction of the left vocal band. Dr. J. W. Warren, assistant in physiology, was requested to come and witness this unusual sight. The ether sponge had been removed from the dog since the beginning of the experiment, and by the time Dr. Warren was ready to look at the larynx the animal was somewhat out of its influence.* At all events, on stimulating the nerve a second time, the familiar closure of the glottis was manifested instead of the dilatation so evident a few moments before. On the assumption that the degree to which the animal was narcotized might have something to do with these phenomena, a large quantity of ether was again administered. After the dog was profoundly under its influence, the nerve was irritated a second time, when both Professor Bowditch and Dr. Warren observed the *ab*duction of the vocal band, which was more marked in proportion as the stimulation was more intense. On removing the anæsthetic the dilatation became less and less as the animal regained its consciousness, when finally a contraction of the glottis supervened. The different stages in this experiment were readily followed by watching the dog's vocal bands while, at the same time, the recurrent nerve was irritated at intervals of a few moments. Between extreme dilatation and forcible contraction, under these circumstances, there seemed to be a neutral point, so to speak, when the stimulation produced merely a vibratory movement of the vocal band; but this was soon succeeded by an attempt at contraction, and this in turn passed into a frank and decided closure of the glottis as the animal, as before mentioned, came out of the effects of the ether. Similar results followed stimulation of one or the other of the divisions of the left recurrent nerve. These branches, as was shown by subsequent dissection, and as you will see on the specimen, united into one nerve fifteen millimetres below the cricoid cartilage, and from this point to the larynx it is a single nerve. The effects of irritation applied to the right recurrent (which was single) agreed with those on the left. Stimulation was effected by means of an ordinary induction apparatus,* the intensity varying from 1 to 40. In general, however, in this and in subsequent investigations on other dogs, the intensity used was from 1 to 8, never over 10, and generally about 3. The experiment many times observed on this animal was repeated, with confirmatory results, on eight different dogs. But the extent and the force, it must be mentioned, with which the vocal bands were *ab*ducted differed in different dogs. In five instances the arytenoid cartilage was rotated outward so forcibly that the vocal band lay flat against the wall of the larynx. Moreover, in one case there was a marked *ab*duction of the vocal band on the opposite side. In other dogs a *mixed* movement was observed—that is, the band approached the median line anteriorly, while a simultaneous contraction of the posterior crico-arytenoid muscle took place posteriorly, which left, in the respiratory portion of the glottis, a large triangular opening, the glottic picture resembling an exaggerated form of paralysis of the arytænoidæus transversus muscle. These phenomena were observed after the recurrent nerve had been cut and its peripheral end stimulated as well as when the nerve was intact. Usually when a young dog is under ether the vocal bands are seen moving rhythmically and regularly with respiration. Occasionally, in this condition of profound narcosis, we noticed that, although the animal was breathing, the respiratory excursions of the vocal bands had entirely ceased, the glottis remaining widely dilated. As soon as the respiratory movements had recommenced, irritation of the recurrent nerve was followed by the usual *ab*duction of the vocal band, an action we have become accustomed to regard as the normal one, *provided* the consciousness of an animal is completely abolished by sulphuric ether. The most striking demonstration, however, of this dilatation of the glottis is obtained by placing an electrode on each of the recurrent nerves and irritating the two nerves at the same time. Both arytenoid cartilages are now rotated simultaneously outward, the glottis is held widely open during the stimulation, and the effect is one not soon to be forgotten. Krause † has noticed the difference in the mobility of the vocal bands according as the animal was more or less narcotized. Just in proportion as consciousness was deadened, the *ad*ductors became sluggish. We have repeatedly observed the same effect when the dog was under morphine, chloral, or chloroform, but we failed with all these agents to obtain the total abolition of the action of the constrictors, on irritating the recurrent nerves,

* Not in any of these experiments sufficiently to feel pain.

* The electrical apparatus was the same as that used by the writer in former experiments, to which the reader is referred for an explanation of the terms employed. (See "Experimental Researches on the Tension of the Vocal Bands," "Trans. of the Amer. Laryngological Association," 1883, p. 121.)

† "Experimentelle Untersuchungen und Studien über Contracturen der Stimmbandmuskeln," Virchow's "Archiv," Band 98, 1884.

which is so marked when large quantities of ether, which can be given with safety, are administered.

From the enormous development of the respiratory laryngeal muscles of the horse we conjectured that their contraction might be even more easily called forth than that of a dog's. In this we were disappointed in the single experiment we have performed on this animal. Chloroform was the anæsthetic used. An incision was made in the thyro-cricoid membrane, through which the finger was inserted and directed between the vocal bands. On irritating the recurrent nerve the finger was tightly squeezed by the contracting glottis. It is probable, however, that if ether had been employed instead of chloroform, and the horse thoroughly saturated with it, we should have felt the glottis dilate and not contract. We were indebted to the Harvard Veterinary College for this observation, and chloroform, for reasons of convenience, is the only anæsthetic used in that institution.

With a view to ascertaining whether certain fibers in the recurrent were more vulnerable than others, we undertook a series of observations of which the following may be taken as the type: The nerve was exposed and a small crystal of chromic acid was laid upon it. The electrode being placed below this point, the nerve was irritated at intervals while the chromic acid was working its slow destruction. In order to watch the effect upon the vocal band, the dog was arranged as in the previous experiments. When the animal was thoroughly etherized, the results did not differ materially from those already described. Stimulation produced *ab*duction of the vocal band. As the destructive process of the acid progressed, the vocal band gradually became completely paralyzed. But, even after the respiratory movements of the vocal band had entirely ceased, irritation was followed by an outward rotation of the arytenoid cartilage. This was only occasionally seen, and lasted but a moment, for, as soon as the conductivity of the nerve was completely destroyed, stimulation naturally produced no effect. We can only say that under these circumstances we were able to produce an *ab*duction of the vocal band as long as *any* action at all was produced. How early or how late in the destructive process the *ad*ductor or phonatory filaments were attacked we know not. Being few in number (probably) as compared with the respiratory filaments, and as ether, as we have shown, arrests so effectually their action, we can not say here whether there was a "proclivity" of either the one set or the other to become affected. We simply demonstrated that the *ab*ductors held on to the last moment, for, as long as a single nerve-fiber of any kind was left intact, we got a contraction of the posterior crico-arytenoid muscle. When the destruction of the nerve was complete, the vocal band stood motionless in the cadaveric position.

In proceeding now to a new order of experiment, we are able to record the endurance of the respiratory filaments contained in the recurrent laryngeal nerve, while those destined to supply the phonatory apparatus were altogether unable to respond to stimulation. We took a small, young dog, exposed the left recurrent nerve, and carefully passed a thread through the middle of it. The two ends of the thread were tied together in order to prevent its slipping out, but no pressure was exerted on the nerve itself. The object of the thread was simply to act as a foreign body. It was hoped that inflammation might thereby be excited, and, as the respiratory or phonatory fibers were the more readily attacked, the effect of an irritation applied to the nerve below the thread would be followed by certain derangements of motion of the vocal band. After the thread had been secured in the nerve, the parts were restored as nearly as possible to their normal situations, and the incision in the neck was sewed up. Inspection of the glottis showed that both vocal bands were moving normally with respiration. The following day the dog was again etherized and the glottis examined. No apparent change had taken place in either the appearance or natural mobility of the parts. The nerve was not disturbed. Since the thread had been introduced in it the nature of the dog had undergone a change. From having been a confirmed howler he had become a model of propriety. This happy improvement in his disposition lasted until he was destroyed. The quieting effect of a thread in the recurrent nerve has been noticed in many dogs subsequently. At the end of a week, the dog having been etherized and the glottis inspected on four different occasions, he was again placed under the anæsthetic. As soon as a cannula could be placed in the external jugular vein chloral was injected into it and the ether removed. It is important to remember that in the following experiments the animal was chloralized and not under the influence of ether. A slight but evident change was now observable in the vocal band corresponding to the nerve operated upon. Although the arytenoid cartilage of this side appeared to move with respiration as naturally as did the right cartilage, the anterior portion of the left vocal band seemed to have lost its "tone"; it did not come up with the same "snap" on expiration as its fellow. On opening the incision in the neck, the nerve was found imbedded in a considerable mass of inflammatory tissue, from which it was impossible to separate it. After exposing the nerve below this point, it was placed in a shielded electrode. Irritation with an intensity varying from 1 to 10 produced *ab*duction of the left vocal band, and cessation of its respiratory movements, the band remaining in the position of deep inspiration as long as the stimulation was kept up. On ceasing the irritation the respiratory movements went on as before. The right vocal band was in no way influenced when the left recurrent was stimulated with an intensity not exceeding 10. When, however, a more powerful stimulation (15) was employed, the right vocal band was brought to the median line (phonatory position), while at the same time the left band was pulled outward. We have, then, here a double effect: *ad*duction of the vocal band on the healthy side, and *ab*duction on the side where some alteration had taken place in the nerve fibers; or, in other words, the normal action of constriction of the right side was manifested while the left band was *ab*ducted, owing to the degeneration of the phonatory fibers, the respiratory filaments remaining unharmed; and, consequently, the respiratory muscle alone responded to the stimulation. The right vocal band was now paralyzed by section of the right

pneumogastric, the band coming to a standstill in the cadaveric position, or the position we are accustomed to see in cases of "recurrent paralysis." Stimulation applied to the right recurrent resulted in a smart closure of the glottis, effected by the right vocal band being brought forcibly against its fellow, as well as by the contraction of the arytænoidæus transversus, which approximated the two arytenoid cartilages. It could not be accurately determined whether the anterior portion of the left band contracted or not, as even a feeble irritation produced such a rapid and complete closure of the laryngeal aperture. If the closure of the left vocal band was brought into action, it was very slight; it was evident that the closure of the glottis was chiefly effected by the contraction of the constrictors on the right side, and by the arytænoidæus transversus muscle. The electrode was again changed to the left recurrent below the insertion of the thread. Stimulation was followed by the same outward rotation of the left aryteuoid cartilage as was observed in the first experiment. There was also a marked movement of the right arytenoid cartilage toward its fellow, as if by the contraction of the arytænoidæus transversus muscle. The action of this muscle was prominently brought into play in the next experiment, when the peripheral end of the left recurrent was stimulated, after section of the nerve below the thread. Both vocal bands were now paralyzed and standing in the cadaveric position. All avenues to the brain were thereby cut off except through the anastomoses of the terminal branches of the recurrent with those of the superior laryngeal, and, perhaps, also with those from the pharyngeal plexus. Irritation of the peripheral end of the left recurrent produced both a contraction of the left posterior crico-arytenoid and transverse arytenoid muscles. That is, there was a distinct outward rotation of the vocal process of the left arytenoid cartilage, and an approximation of both arytenoid cartilages at the same time.

Positive as were the results of this series of experiments, we lay no stress upon them. If they are of any worth, it will be by suggesting to others some better method than was here employed, for all our attempts to verify the observations have failed. Even when the thread had been previously soaked in a one-per-cent. solution of chromic acid it did not cause any material disturbance when introduced through the nerve and retained there for many days. The only change noticed was that, in some of the dogs, a more powerful stimulation was required to produce a contraction of the vocal muscles through the nerve operated upon than in the opposite healthy side.

CONCLUSIONS.

The principal fact herein demonstrated is, to our mind, the power and the endurance of the posterior crico-arytenoid muscles and of the nerves which supply them. We have spoken of the theoretical reasons: (1) The physiological importance of these muscles; (2) their belonging to organic life; (3) their extensive nerve-supply, all of which would tend to preserve their functional integrity. Moreover, if it be true that there is a "proclivity" of the *ab*ductor fibers to become diseased, and that unilateral paralysis of the abductor muscle is such a common and harmless lesion, should we not expect, theoretically, that bilateral paralysis of this muscle would occur more frequently? Yet there can be no dispute whatever that bilateral paralysis of the posterior crico-arytenoids is a disease as rare as it is grave.

Now, with regard to these muscles being *extensors*, and, like the extensors in other parts of the body—the forearm, for instance—more liable to succumb to disease than the flexors, we would ask this simple question: Why should the terms "extension" and "flexion" be applied to the rotation of the arytenoid cartilages? The principal office of the posterior crico-arytenoids is to maintain the respiratory patency of the glottis. From the beginning to the end of life they are in a state of semi-contraction—holding the glottis open. They come, therefore, just as near being flexors as extensors; but, as a matter of fact, they are neither the one nor the other in the ordinary acceptation of these terms as applied to muscles of the general system. They are *respiratory* muscles carrying on a special function. One might as well speak of the movements of the pupil as extension and flexion, or compare the diastole of the heart to the extension of the forearm, or its systole to the bending of the little toes. Muscles are analogous as they discharge analogous functions. We recognize no more analogy between the posterior crico-arytenoid muscles of the larynx and the extensor communis digitorum of the forearm than there is between "respiration" and "prehension." If we wish to seek muscles that are analogous, let us turn to other respiratory muscles and ask how they are affected by disease. In diffused, progressive diseases of the nervo-muscular system we know that of all muscles, except the heart itself, those belonging to the respiratory system are always the last to be attacked, and there is no valid reason why the respiratory muscles of the larynx—either one or both—should offer an exception to the rule, especially as they are the most important of all.

We propose to investigate this subject from a clinical aspect at some future date, when, perhaps, the positions which immobile vocal bands assume may be sufficiently explained without attributing to a wise and conservative nature a "proclivity" to attack one of the most vital muscles of the human system.

DISCUSSION.

J. Solis-Cohen.—It is a great honor to the American Laryngological Association to have had this valuable paper read before it, and I believe it will be an historical paper. These experiments will be subjected to criticism, and their verification will become a matter of history in the controversy now existing in the laryngological world as to the liability of these abductor fibers to become diseased sooner than the adductors. The dogmatism with which the assertion has been made seems to have almost paralyzed laryngologists, for, with the exception of myself, I hardly know of any one who has ventured a word against it. Even last year, when I presented a case opposing the theory, and showed a picture of the larynx, it was simply in deference to myself that not much was said against it. Not a single member of the Laryngological Association, even of those living in Philadelphia, where the patient was, would accept my invitation to the members to see the patient for himself, and verify the fact that the picture I presented was a correct one. The

only word of commendation I received was from Krause, of Berlin, who wrote me a very interesting letter, stating that he believed my observation was correct, but attributed the lesion to a different cause. I will recall the case for a moment. A man had received a wound in the neck. He had instantly become aphonic, and when I saw him, a few months afterward, one vocal band was in extreme abduction. I took it for granted that the adductor fibers of the pneumogastric had alone been injured. Krause's explanation is this: The injury of the carotid having been attended with hæmorrhage, a clot must have occurred around the pneumogastric nerve, producing compression, which became permanent by the formation of the cicatrices. I do not know where that patient is now. I have seen him several times, and the affected vocal band has remained in extreme abduction.

I have had no experience in such physiological experiments as Dr. Hooper has made; but there is a point he spoke of which receives clinical support. That is with reference to the influence of the facial nerve in sending the respiratory forces to the pharyngeal. We all know the effect of cold on the facial nerve in restoring suspended respiration. I remember a case in which I was called to see a child who had diphtheria following measles. There was great dyspnœa, but I declined to perform tracheotomy, because the child was under two years of age, and I knew that the operation was usually unsuccessful after measles. Knowing the great effect of cold on the facial nerves, in stimulating the facial centers, we placed ice cloths all over the lower part of the neck and jaw up to the ears. Every time the iced cloth was placed around the jaw an inspiration took place, and the physician in attendance, Dr. O'Hara, by his own efforts in keeping this up, saved the child's life. So many times a minute he replaced the cloth. Several pieces of cloth were kept between two pieces of ice. As soon as the piece in position ceased to produce any effect it was replaced by another. So there is a point in which, clinically and physiologically, these facts support each other. The phenomenon of stimulating one recurrent nerve so that its vocal band passes beyond the median line in phonation is, if I remember right, confirmatory of some of Krause's experiments. He states that, when he stimulated one nerve, the vocal band of the opposite side moved also. It would touch the other, no matter what position it was in, whether it was in the median line, in the cadaveric position, or in the inspiratory position. In the case presented by me last year, when the man tried to speak, the sound vocal band crossed away over beyond the median line, and beyond the ordinary position which it occupies in the dead body.

Dr. Harrison Allen said that, in his judgment, the analogy between constriction and adduction, and between dilatation and abduction, was tenable. At least it was of some value in suggesting research. Careful clinical study would often take the place of experiments, and it could be certainly shown from the clinical point of view that adductor muscles and constricting muscles were alike in their ability to withstand disease as compared to the abductors and dilators. The morphologist could also assert that the position of a flexed point in a limb resembled the epiglottis when bent down over the aperture of the glottis, as the extension of the limb-joint might be compared to the erect position of the epiglottis. In the muscles of the limb it was found that the adductors were specialized muscles of the flexor group, and the abductors of the extensor group. Perhaps it might be well to have distinct terms to express this harmony of action between flexion and constriction, but, as part of the study of muscle phenomena taken in a comprehensive sense, the speaker saw much to show that a close association, if not identity, existed.

Dr. Ingals.—In support of the paper in a clinical way, I have had a recent experience, similar to the one related by Dr. Cohen, excepting as to the origin. A gentleman had a cold, over-used the voice during the cold, and in the course of two or three days became completely aphonic. I saw him five weeks later, and found complete paralysis of the left cord, which was fixed in extreme abduction. After two months, there had been no special change in the position. In phonation the sound cord did not cross over as in Dr. Cohen's case; it crossed a little beyond the median line, but very little.

Dr. Delavan desired to unite his congratulations with those of Dr. Cohen upon the paper just presented. It was a most welcome and valuable addition to our knowledge of the subject, and worthy of the highest praise. Reference had been made in the paper to a motor center for the human larynx. Since he had first called attention to the existence of such a center several important contributions had appeared which tended still further to establish the fact; he hoped that sufficient clinical and pathological evidence would soon be accumulated to place it beyond a doubt.

Dr. Hooper.—I have only attempted in this paper to study this subject on general physiological and experimental grounds. Clinically it seems to me a difficult question and one in which there are many sources of error. We are dealing, in the first place, with one of the most complicated organs in the body, and in using the laryngeal mirror we are looking at things in perspective, which are in almost constant motion. It is often impossible to say whether a vocal band stands motionless in the median line or a few millimetres off from it. If we call every paralyzed vocal band we see a paralysis of the posterior crico-arytenoid muscle, we can multiply such cases very rapidly. Not only is the theory that there is a proclivity of the posterior crico-arytenoid fibers to become diseased contrary to nature, but the dogmatic manner with which it has by some been advanced ought of itself to cause us to doubt its accuracy. I should feel sorry to have an association like our own subscribe to this notion on the very shallow evidence we have at present.

I must thank you for the attention you have given my paper. What there is in it which you say has interested you is chiefly due to the perfect arrangements of the physiological laboratory of the Harvard Medical School for pursuing such investigations. The professor of physiology, Dr. Bowditch, and others connected with the department, are always ready with their time and advice to aid those who are carrying on any kind of research, and I shall, therefore, convey your kind expressions of interest to the quarter where they really belong.

BRONCHIAL BREATHING A SIGN OF PLEURITIC EFFUSION.

By G. M. GARLAND, M.D.,
ASSISTANT IN CLINICAL MEDICINE, HARVARD UNIVERSITY.

The differential lines between pneumonia and pleuritic effusion are ordinarily so clearly and closely drawn that a mistaken diagnosis between these two diseases would appear almost evidence of criminal ignorance. And yet such mistakes are made frequently and by skillful observers. Cases present themselves wherein all the physical signs fail of conclusiveness, and even the exploratory needle leaves doubt as to the actual state of affairs behind the chest-wall. I wish in this article to speak of one group of symptoms which, above all others, is misleading in pleurisy, and which has, within my own experience, been productive of mistaken diagnosis in several instances.

As ordinarily stated in the text-books, the entrance of

fluid into the pleural sac obtunds the signs of an air-containing chamber. In proportion as the pleural tide rises the air-sounds are dulled, until the negative list includes:

Diminution or Absence of	Respiratory murmur.
	Vocal fremitus.
	Vocal resonance.
	Whispered resonance.
	Percussion resonance.
	Flexibility of chest-wall.

Silence reigns over the invaded region. This picture is typical and obtains in the majority of cases. Occasionally, however, a patient appears with many signs of an effusion, but, in place of diminished respiratory symptoms, he exhibits bronchial breathing and whispered bronchophony all over the dull area. Naturally such symptoms lead one's thoughts directly to pneumonia, inasmuch as they are declared to be indicative of pulmonary consolidation, and are even specified as eliminative of pleural fluid.

Of late years, however, records of such cases have appeared in the journals, and Baccelli, of Rome, not only has described the symptoms, but has made the occurrence of whispered pectoriloquy with an effusion in the chest a differential point between a serous exudation and empyema.

Now, the question arises how to explain this phenomenon of bronchial breathing over a fluid effusion. Bacelli says that an effusion which is homogeneous in character—*i. e.*, serous—will take up and transmit the vibrations of the collapsed lung more readily than a purulent exudation, which is heterogeneous in character, and hence the occurrence of audible whispers in the former case and their absence in the latter. This explanation was eagerly seized by clinicians all over the world, and carefully studied until it was found that it could not be supported by facts. Whispered pectoriloquy occurs with purulent as well as with serous effusions, and thus Bacelli's theory falls to the ground.

In my own study of these eccentric symptoms I have arrived at certain conclusions which I desire to submit to the judgment of others. In the first place, I have noticed that bronchial breathing and whispered pectoriloquy have only occurred with effusions of considerable size. I can not lay down any boundaries for the amount of fluid necessary to produce them, and I imagine this amount would vary with other conditions of the chest-wall and lung. In all the cases where I have observed these signs, however, the effusion has reached *at least* to the third rib in front, and in some instances still higher. Secondly, I can not reconcile my mind to the theory that the sounds heard are transmitted through the fluid. Water does not readily take up vibrations from the air. Two stones struck together in the water cause powerful vibrations of the same, but struck together above the water, the sound is inaudible to a submerged ear. We know that some heart-murmurs are transmitted long distances. I have traced such murmurs along the spine from the occiput to the sacrum. Now, when a murmur is heard in the lumbar region, are we to suppose that it has taken the short cut through diaphragm, stomach, pancreas, and bowels to our ear? Sound vibrations, like electrical waves, travel best along lines of least resistance, and such lines for the heart-sounds are found along the ribs and spinal column. The same argument holds good for the bronchial murmur of pleurisy. As an effusion begins to form, the breath-sounds fade out. They are not adapted to pass through the water, nor are they strong enough to overcome other lines of resistance. That bronchial breathing is present may be proved by listening to the lung above the effusion, and especially high up between the shoulder-blades behind. Two conditions might still bring these vibrations to our ear when placed over the fluid. Should the murmur become strong enough to push its way along the ribs, we should hear it; or, if the tension of the chest-wall should be increased in any way so as to convey their vibrations more readily, we should obtain bronchial breathing over the fluid. A telephone works satisfactorily according to the delicacy with which the tension of the tympanum is adjusted to the vibrations of the impinging voice. As an effusion of fluid in the pleural cavity increases in size, its weight puts the chest-wall in a state of increased tension. The intercostal spaces are obliterated—that is, they are stretched more or less taut. In such a condition the vibrations which are thrown against the upper and the back parts of the chest are readily transmitted all over the surface of the affected side and become audible over the dull area.

Recognizing this fact, therefore, that bronchial breathing may be conspicuously associated with pleuritic effusion, we find that this sign is bereft of differential value. Instead of a light to illumine the diagnosis, it becomes a dangerous shoal, upon which an opinion may be and often is wrecked.

I need not relate the instances where this bronchial breathing has, within my experience, led observers astray, but I will merely refer to one illustrative case: I was called in consultation to a young lady, twenty-three years of age, who was thought to have pneumonia in the left side. Upon examination, I found the signs of a pleuritic effusion, except the presence of loud bronchial breathing and whispered pectoriloquy, all over the dull area. These signs were so marked that they almost shook my interpretation of the other signs. The impulse of the heart, however, was palpable and visible about one inch beyond the *right mammillary line*, and the young lady said she had noticed this beating herself for several days, but had not mentioned it for fear of being laughed at, if she said her heart was way over there. I tapped the chest, plunging my needle into the region of bronchial breathing, and drew off about five pints of serous fluid. Now, the displacement of the heart was the key-note to this case, and removed from my mind the doubts raised by the auscultatory signs. It is, of course, possible that a congenital transposition of the heart, or its retention in an abnormal position by adhesions from an old pleurisy, may render the diagnosis difficult. Such cases have occurred. Usually, however, the associated transposition of other organs or the history of the case will enable one to solve the problem. It should be laid down as a maxim that the determination of the apex impulse should be *obligatory* in every examination of the chest, no matter what the disease or what the nature of the other signs may be. The man who makes this his habit will often find occasions to congratulate himself upon escape from error.

HERPES TONSURANS MACULOSUS.

By GEORGE T. ELLIOT, M. D.,

ATTENDING PHYSICIAN TO THE DEMILT DISPENSARY; ASSISTANT VISITING PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

The name herpes tonsurans maculosus is given to an acute eruption disseminated more or less over the entire body, and caused by the vegetable parasite, the *Trichophyton tonsurans*. It is comparatively infrequent in its occurrence here, and, though it has a common origin with ordinary ringworm, yet it differs from this in the manner of its invasion, the acuteness of its development, the extent of surface implicated, and in its general course. The individual lesions retain, however, the salient characteristics of the ordinary form.

The conditions under which it may occur are the same as those favoring the development of ordinary ringworm—viz., damp lodgings, clothes, etc.; immediate infection, etc. Its own power of infection, in the earlier stages at least, does not seem, however, to be very active, and, in the many cases which I have observed, I have not yet been able to trace its having been communicated from one person to another, though all conditions for such communication were present. In fact, one of the patients whose cases are reported here, was for nearly two weeks in constant contact with another lady before the disease was treated, and still no infection occurred. The other patient, a boy, slept with his mother during the entire time that the disease was present, and yet she remained free from it.

In all probability an outbreak of herpes tonsurans maculosus is due to multiple infection. The spores of the parasite, obtaining access to the skin at many points, develop rapidly under suitable conditions. The simultaneous outbreak of many lesions, it may be on one part of the body, as an upper or lower extremity, or on various parts widely separated from each other, and many other factors, speak for this manner of origin. These primary lesions may, however, again serve as foci of infection, inasmuch as the scales of epidermis, being detached by the movements of the body, the friction of the patient's linen, carry the spores to other as yet unaffected portions, where the process begins anew. A succession of outbreaks thus appears until, in a short time, the patient is covered with the lesions in all stages of development.

There is no particular localization to the disease, and no portion of the body is invulnerable to its attack. The backs and flanks are, however, usually more thickly studded with the lesions, but they are also found in great numbers on the face, neck, chest, abdomen, and extremities. The outbreak of the affection may be preceded by malaise, some fever, loss of appetite, and symptoms of general disturbance. In the course of the disease the irritation and consequent loss of sleep in children may give rise to serious anxiety.

The eruption first appears upon the portion of the body affected in the form of small papules about as large as a millet-seed, of a pale-red color, which disappear on pressure, and are slightly elevated. On those parts where there is much perspiration the color of the lesions is a dark red. Shortly after the appearance of the papules—it may be only a few hours—peripheral growth has ensued and slight exfoliation of the epidermis will be observed in the centers, while the edges remain smooth and red. The lesions are at first circular, but, as they grow larger, many become oval in shape, their long axes lying in the direction of the cleavage lines of the skin. Their development is at first rapid, and in the course of a week or ten days they attain the size of a twenty-five-cent piece, or even larger. Where the edges of two or more of the lesions come together, the portions which were in contact disappear and a gyrate form of eruption remains. As the lesions increase in size their edges become more elevated, are of a bright red, and scaly, fading gradually away into the surrounding tissue. At times vesiculation is observed. The central portions are more or less scaly and in process of involution, but in the larger lesions these squamæ have ceased forming and the skin may be found perfectly normal. As they become older they acquire a dirty, light-brown color, and they approach more nearly to a typical ringworm. Many of the lesions, however, do not follow this course, but abort and disappear a few days after their first appearance. The itching of the eruption is not very severe, unless, through improper treatment or from other causes, a consecutive eczema or dermatitis complicates it.

If left to itself, the disease runs its course in from two to six months. The edges flatten out, the erythematous condition disappears, desquamation occurs, and the skin becomes again normal. Slight pigmentation may remain for a variable length of time. One spot often remains, especially on those parts of the body which are well protected, and may serve as a focus for reinfection. If the epidermis scales are examined under the microscope, the mycelia and conidia of the *Trichophyton tonsurans* will be found, but very sparingly, in the younger lesions. In ordinary ringworm, any small epidermis scale will show large numbers of the parasite, but a search for hours through squamæ taken from young spots of herpes tonsurans maculosus will be rewarded by the discovery of only a few spores, and perhaps a beginning mycelial formation. As the lesions, however, become larger and approach more nearly the type of ordinary ringworm, the presence of the parasite is easily demonstrable.

The diagnosis presents no special difficulty to the dermatologist, and should not to the practitioner in general, if the determining characteristics of ordinary ringworm are kept in mind. Only at its first appearance can it be mistaken, but its development is so rapid that ordinary observation very soon clears up any existing doubt as to the nature of the eruption. Should an eczema complicate the disease, the finding of a fresh and uninjured lesion will demonstrate the real disease present.

The histories of the two cases which I desire to report are as follows:

Case I.—Miss —— states that the eruption from which she suffers has existed for two weeks, and that during that time she has received no treatment. Two days before I first saw her, on December 20th, she consulted Dr. Robert Abbe, who kindly referred her to me. She informed me that about six months before she had had on the outer surface of the left thigh a circular spot

with red elevated edges, the center of which was covered with squamæ. It itched slightly, but caused no special trouble, and finally disappeared, though it received no treatment. The eruption with which she was afflicted at the time I saw her was preceded by some feeling of malaise and general disturbance, and showed itself simultaneously on neck, flanks, and thighs, under the form of small, erythematous, slightly itchy papules. They were rather closely aggregated, and peripheral enlargement took place rapidly. At first she paid little attention to the eruption, until the continued appearance of fresh lesions and the growth of the primary ones suggested to her the advisability of consulting a physician. On examination, the following condition was found: On the face and neck, and along the margin of the hair, on the shoulders, arms, and backs of the hands, the entire trunk, the thighs as far as the knees, and on the left heel, there was an eruption of papules, circular, oval, and gyrate spots of all sizes and in all stages of development. In the axillæ and on the mons Veneris were likewise a few lesions. All the characterizing objective symptoms were present, and there was no hesitation in deciding upon the nature of the affection. The largest lesions, situated on the left thigh near the crest of the ilium and on the back, were of the size of a twenty-five-cent piece, and oval in shape. The itching was not very severe, but still enough to cause some discomfort. Some of the scales from the younger lesions were examined under the microscope, but beyond a few spores nothing was found. An anti-parasitic treatment was immediately instituted, consisting of salicylic acid dissolved in alcohol. Two days later, December 22d, the patient reported slight improvement, but many new lesions had appeared on the abdomen, mammæ, etc. Those on the back and thighs were improved.

December 24th.—Improvement was more marked. No new spots had appeared, and a decided change could be seen in those already present. Some had completely disappeared, while even in the larger ones the prominence of the edges and the erythematous condition had greatly decreased. Treatment was continued.

30th.—The disease was substantially cured. No new lesions had appeared since her last visit, the erythematous condition and elevation of the edges had disappeared, and there remained only here and there some roughness of the skin, though in many places where the disease had been present the skin was already normal in appearance. Treatment was suspended and an indifferent ointment was ordered, to relieve the slight irritation which the lotion had produced.

The patient returned, however, ten days later. There had been an outbreak on the inner surface of the thighs, and perhaps a dozen new spots had appeared. A few days of the treatment brought these to an end, and there has been no new return of the disease.

Case II.—In May, 1884, while I was attending the dermatological class at the Bellevue Out-door Department with Dr. W. G. Robinson, a boy of twelve presented himself for treatment, complaining of an itchy eruption situated principally on the trunk, and to a lesser degree on the extremities and neck, which had first appeared one week previously. Any description as to its first appearance, or his condition at the time, could not be obtained.

On removing his clothes, an extensive eruption was found covering the portions of the body already mentioned, and consisting of lesions of about the size of a five-cent piece. They were rather uniform in size, and to a large extent were undoubtedly of the same age. They presented the characteristic objective appearances already mentioned as marking an outbreak of herpes tonsurans maculosus. They were all of a light-brown color, and little erythema was present, but this was evidently due to his decided aversion to the laws of cleanliness. Anti-parasitic treatment was immediately instituted.

The patient returned in four days, and it was found that the spots had not increased in size, that no new ones had appeared, and that the itching had diminished to a great extent. He was directed to continue treatment and to return in a week. On presenting himself after that time all signs of the disease were gone. There was only a slight roughness of the skin remaining.

As may be seen, these two cases presented substantially the same appearances and course. In both the disease was comparatively recent, and, though existing in the vicinity and on parts covered with hair, had not been communicated to the hair follicles and hairs. If this had occurred, the cure of the eruption would necessarily have required a greater length of time and more special treatment.

The treatment of this form of disease caused by the *Trichophyton tonsurans* is in substance the same as that used in the other forms, only some care should be taken in the choice of the anti-parasitic. It should be borne in mind that an application limited to the lesions alone or to a certain number of them at one time will be useless; it is absolutely necessary to apply the anti-parasitic remedy to the whole body, even upon those portions which appear perfectly normal. It is important to check the progress of the disease as quickly as possible, and, the longer it is temporized with, the greater the difficulty in curing it, and the greater the risk that an eczema or a dermatitis may arise to complicate it. After the arrest of the affection, and there is a certainty of the death of the parasitic spores, the skin should be protected by the inunction of some bland salve, and powder should be freely used. More or less exfoliation of the epidermis occurs, and the skin becomes normal in from a week to ten days.

23 East Thirty-first Street.

THE THERAPEUTIC SIGNIFICANCE OF THE CERVICAL FOLLICLES.

By SIMON BARUCH, M. D.,
GYNÆCOLOGIST TO THE NORTHEASTERN DISPENSARY, NEW YORK.

(*Concluded from page 720.*)

The subject of uterine catarrh is referred to incidentally and not with a view to discuss it here, because I desire to point out the different conditions of the glands in disease of the cervix. In the latter atrophy is the exception, cystic degeneration being followed by it only after a very long existence of the process. A different method is indicated in cervical catarrh; the glandular structure must be reached by the treatment if we would succeed. The cyst-like distension must be removed by laying open the walls of the glands. The latter being very numerous, and their walls somewhat tough and resisting, the application of remedies should be preceded by scarification of the mucous membrane and submucous glandular structure, and in the more obstinate cases, where no cellulitis coexists, the sharp curette would answer a good purpose. Whether the catarrh be corporeal or cervical, therefore, the glandular structure is the secreting structure, and it must be reached by the means indicated. The patient is carefully prepared by reducing any pre-existing cellulitis, and softening infiltration

in the annexa by the usual remedies, rest, hot douches, glycerin tampons, etc. If the disease is extensive, or the patient very nervous, an anæsthetic may be required. While the patient lies in Sims's position, the cervix and vagina are thoroughly irrigated by an antiseptic solution; a Wilson's or Goodell's dilator, previously rendered aseptic, is introduced into the cervical canal for the purpose of dilating it to the required caliber. A blunt-pointed bistoury is now made to scarify the canal longitudinally and somewhat deeply. If a sharp curette be now made to scrape over the surface, it will bring away more or less glutinous, glairy fluid from the ruptured cystic follicles, and perhaps some *débris* of the latter. A thorough swabbing with tincture of iodine, after bleeding has been somewhat checked by pressure, completes the operation. A carbolized glycerin tampon of cotton or oakum will neutralize the discharge and allay irritation. Hot antiseptic douches may afterward be resorted to daily and the treatment continued on ordinary principles. By adopting the course here mapped out, we follow the teachings of modern surgery, which are applicable in gynæcology as well. The method here proposed may appear somewhat heroic, but we have a heroic disease to deal with. Moreover, it is well known that even more radical measures have been advocated and practiced for the cure of obstinate cervical catarrh. Schroeder has recommended very highly, for the cure of those obstinate cases in which great glandular enlargement of the mucous lining exists, the excision of the entire diseased mucosa. He makes an incision on each side of the cervix, so as to divide it into two separate halves, up to the inner os. The mucous membrane and glands are now removed by an incision passing through the cervical parenchyma; each lip is turned upon itself, and its folded surfaces are stitched together, so that the entire cervix is covered within and without by squamous epithelium. Olshausen reports eighty cases, and he regards this operation, done under continuous antiseptic irrigation, as not only free from danger, but remarkable in its results. Hegar, Kehrer, and others have devised similar operations. All these surgical procedures prove the great significance of the cervical follicles, for it is evident that the removal of the mucosa containing them is regarded as the most essential element in the treatment of intractable cases of uterine catarrh.

The radical cure of so-called hypertrophy of the uterus, chronic metritis in the various forms in which the cervix is involved and involution has been interrupted, has frequently been accomplished by A. Martin ("Arch. für Gynaekologie," 1879, 488). The failure of all local therapeutics by caustics, injections, etc., has placed this malady in the category of incurable diseases. Carl Braun had shown in 1864 that involution was hastened by amputation of the cervix, and Martin followed and confirmed Braun's ideas. He operated in seventy-two cases, chiefly complicated with ectropium, erosions, and ulcers of the portio vaginalis, with perfect cure in sixty-four cases; portions 3 to 4 ctm. long were removed, and in the course of a few weeks complete involution resulted. Kehrer and Schroeder, also Hegar, cited similar experiences during the discussion, the former citing forty to fifty cases in which he obtained good results by excision of triangular pieces on each side and union of the edges (is this not akin to Emmet's operation?).

In this country these heroic operations have not received much approbation, first, because they mutilate and disfigure the cervix uteri more or less, or, when the latter is entirely removed, it becomes difficult to retain the uterus in position; and, second, because we have in Emmet's operation a superior procedure in the class of cases referred to by Schroeder and Martin, which, occurring in parous women, are almost invariably connected with lacerations of the cervix. There had been no operation devised which removed diseased tissues and at the same time restored the cervix to an almost normal form and condition after the traumatism of childbirth before Dr. Emmet gave to the world his now classical operation of trachelorrhaphy. Indeed, to him we owe the recognition of the fact that a lacerated cervix completely or partially healed, combined with more or less cellulitis, is at the bottom of the great preponderance of uterine diseases, outside of neoplasms and malpositions. But what Dr. Emmet has taught, and is still teaching with more emphasis than all else, and what yet is more neglected and misunderstood, is the *principle that his operation is not intended as a plastic procedure for the reunion of the torn edges of the cervix, but that its aim and scope lie far beyond the mere æsthetic effect, in the removal of diseased tissues, to whose presence are due the local and especially the reflex symptoms which we are called upon to treat.* It is remarkable how slowly the appreciation of this principle and of these facts, which we daily observe here, has dawned upon gynæcologists abroad. It is not so surprising that lacerations of the cervix were not recognized in England so long as they were sought for through the old tubular speculum, because only their exposure by Sims's speculum, and the approximation of the torn edges by means of tenacula, could convince skeptics. In Germany, however, where Sims's and Simon's retractors are in constant use, Emmet's views have not received that warm appreciation which is accorded to them in this country. The reason is obvious to any one who is familiar with German gynæcological literature, which contains the most garbled descriptions and most erroneous views concerning the operation for lacerated cervix. For instance, Olshausen says ("Klinische Beiträge zur Gynaek. und Geburtshülfe," 1884, p. 32), in referring to Schroeder's operation: "We agree with him that, in the so-called laceration-ectropium, it is more safe, and at the same time a not more serious procedure, to extirpate the diseased mucosa than to make the Emmet 'ectropium operation.' We have, therefore, not been able to become friendly to the latter, and have only executed it a few times." *Dr. Emmet's operation is really intended to* "extirpate the diseased mucosa." Hegar tells us ("Hegar und Kaltenbach," 1881, p. 539): "Emmet hopes, by simple union of sutures, to relieve the patients of all their troubles and to produce a recession of the tissue changes"; and Hegar dismisses the description of the operation for lacerated cervix in these words: "While the assistant holds the lips of the os uteri on a stretch, the edges of the tear are freshened smoothly and thoroughly by knife or scissors; the freshened surfaces are brought together by needles, etc. As the

operation is only slightly painful, chloroform is usually dispensed with" (!).

These brief references from prominent German authors afford ample evidence of the fact that the principle as well as the technique of Emmet's operation is not understood. Any one who has seen Dr. Emmet operate will smile when he reads the description given by Hegar. Whoever has seen Dr. Emmet labor from ten minutes to an hour, or even longer, over a lacerated cervix, digging and snipping away diseased glands and cicatricial tissue, knows that it is not the slight operation described by Hegar, and will appreciate how egregiously his work is misrepresented abroad. We can not wonder that the imperfect knowledge of this valuable surgical procedure has failed to establish its usefulness. Only a few days ago I heard Dr. Emmet inveigh bitterly against the practice of superficial denudation. He said that he believed the operation was doing more harm than good, because every novice deemed himself competent to perform it without really understanding the essential principle, which was "*to remove the cicatricial plug.*" He also said that he never operated for lacerated cervix unless there were symptoms indicating the necessity for the procedure. While I appreciate fully the fact that the mere existence of the laceration of the cervix is not the exciting cause of those symptoms which keep the poor woman in a constant state of invalidism, I do not believe that the latter are invariably, or even frequently, due to "a cicatricial plug," but that at least the catarrh and the erosion, and probably also the reflex symptoms, owe their origin to another factor, viz., *disease of the glandular structure*, which is almost invariably present. In those trying cases of cervical catarrh connected with abrasions, hyperplasia of the cervix, and subinvolution, which are the fertile source of ill-health in parous women, and to detail whose symptoms would be to you but an oft-told tale, a lacerated cervix is, as I have said, a frequently co-existing condition, and constitutes, together with more or less pelvic cellulitis, the chief element in the case. That this is a clinical fact is attested by the results of the operation of trachelorrhaphy when properly executed, viz., when it is done not alone for the purpose of restoring the tear, but for the purpose of extirpating the diseased mucosa, with its numerous diseased follicles, down to the healthy parenchyma.

I show you here a specimen of this condition, and you will see one of the glands forming a large cyst, which I have opened for your inspection. All the pathological changes which have been detailed under the general head of cervical catarrh, as involving the mucous membrane, are here seen in an exaggerated form, owing to the obstruction in the circulation of the cervix, the eversion of the lips, and the neighboring cellulitis. Erosions, too, present an additional source of pain and discharge. No application of caustics will cure these cases, for how can we penetrate these callous structures and cyst-walls? We may heal the erosions over by a slow process, squamous epithelium taking the place of the cylindrical or the everted mucous membrane. We may by this means check the secretions from the surfaces within reach of applications, among which nitrate of silver has proved the best, but yet the most harmful eventually, because of the nodular tissue produced by it. Crude pyroligneous acid is much used by the Germans in erosions. But so long as cystic degeneration of the follicles remains, so long as new cysts form, our patient will continue to suffer the backaches and reflex symptoms which render her life miserable. How often women apply for relief under these conditions, and how rarely they receive it by medicinal application, is within the experience of all. But, if we have regard for the true cause of these symptoms, we may afford them relief by simply puncturing the glands separately, or, what is better, by deeply scarifying the entire everted surface, from the inner os to the point beyond the junction of the vaginal covering of the cervix, by radiating incisions. The hæmorrhage may be a little free, but can readily be checked by pressure. The relief from distress is marvelous; and those who have seen these poor women return again and again with the request for the same treatment will not be skeptical regarding my proposition, that *in these diseased and distended glands lies the true cause of the trouble.* Indeed, such cases may, by scarification, hot douches, glycerin tampons, and rest, be almost entirely restored, unless the latter important element can not be gained, as is the case in women who have household or other duties to perform. In the latter, as also in the more pronounced and intractable forms among the better circumstanced, nothing short of trachelorrhaphy will bring permanent relief. But the operation should be thorough; all diseased and hyperplastic structure should be removed, and the cervix should be restored as nearly as possible to its normal size and shape. Unfortunately, there are specialists even who do not in this respect follow the principles laid down by Dr. Emmet, and who, as he says, inclose the "cicatricial plug," whose removal he regards as paramount, in the newly made wound. Among gynæcologists in this city even I have seen few who succeed in giving the cervix after this operation an almost virginal shape, as Dr. Emmet almost invariably does, by first slitting up the angle for the removal of cicatricial tissue, and then bringing the edges together by deep sutures directed toward the angle of the wound and not across from one edge to the other. I am disposed to believe that it is not this removal of the "cicatricial plug" which renders Dr. Emmet's operation in his own hands so signally successful, but that the solution lies in the complete ablation of the *diseased gland structure* which necessarily follows the removal of this cicatricial plug. When a considerable wedge is excised from the angles of the laceration, the surgeon is compelled to resort to free ablation of the thickened flaps, in order to bring them into nice apposition, if he would avoid inclosing a deep gap in the angle; the result is a cervix almost virginal in appearance, which I have seen very few surgeons besides Dr. Emmet able to produce. Let it be borne in mind that the great aim of the operation of lacerated cervix is the removal of the diseased gland structure; let this be unsparingly removed, and this great health-saving and, I believe, life-saving operation will perform its proper function.

There is no treatment for subinvolution which can compare to trachelorrhaphy in brilliancy of results. When we

read the description of this disease, which is now known to be almost invariably only a portion of a complexus of conditions following an imperfect "getting up" from childbed; and if we compare the results of treatment by ergot, tonics, baths, astringents, electricity, and injections, which was in vogue several years ago, with the brilliant results of trachelorrhaphy—we find cause to congratulate ourselves on the fact that we live in this happy era in which surgery counts its triumphs daily.

A few weeks after the wound is healed the uterine canal shows a decrease of depth, there is new life infused into its circulation, involution is re-established, and with it the patient is restored to health. How many weary years have been passed in bootless medication, how many days and months of invalidism have been suffered ere this happy consummation was reached by one brilliant stroke of the surgeon's hand, the sufferer often tells with a sorrowing yet with a grateful heart.

Some twelve years ago I wrote an elaborate article on subinvolution for the Charleston, S. C., "Medical Journal," in which I presented all the remedies which were at that time thought efficient. The recollection of my lengthy account of the therapeutics of this affection has led me to these reflections upon the comparative advantages of the present method of treating subinvolution.

In those cases of cervical disease termed *ulceration* and *erosion* the follicles are again found to enact an important pathological *rôle*. Whether they become more freely developed on their original site, as maintained by Fischel, or whether a new formation of follicles ensues, as is, with more convincing proof, asserted by C. Ruge, the fact is established beyond contradiction that so-called *erosions of the portio vaginalis rest upon a groundwork of glands.* "The entire eroded spot," says Ruge, "is the free surface of a new development of glandular structure upon the normally glandless portio vaginalis; it is covered with a cylindrical epithelium in single layer. At the same time are formed numerous depressions into the tissue, which in single spots are still solid, but soon become hollow, and present themselves as glandular tubes or bags, which, penetrating deeply into the tissue, branch freely and *communicate often with neighboring glands.* From the latter arise partly constricted rounded formations whose inner walls are covered with very fine papillary projections. Repeatedly we found a complete spongy system of glands. The larger glands lie in the mucosa, but even muscular fibers do not hinder their further development. In many cases they reach such massive accumulation that all normal structure is pressed aside. All these constrictions and depressions have cylindrical epithelium which resembles the more superficial. The intervening structure is a young connective tissue permeated by numerous capillary loops. In a peculiar manner we found repeatedly real gland lamina as well as follicle-like formations on parts where the portio vaginalis was covered superficially by normal epithelium and where the papillæ even showed no change. *Their origin is very probably due to the small crypts which in the cervical canal are covered with cylindrical epithelium* [italics mine], but which are sparse in the portio, by means of the deep penetration of these crypts in a direction from within outward toward the portio, whose epithelium they push before them. It is possible that they may partly arise in the connective tissue of the portio vaginalis." From this description of the pathology of erosions it would appear that the follicular structures form their basis, and that it would be irrational to attempt to cure these surface breaches without destruction of the gland-tissue. Strong acids answer a good purpose here, because the diseased surface is within easy reach and may be again and again subjected to treatment.

But the more radical removal by the sharp curette or spoon, or by scissors and knife, as is best done by Emmet's or Schroeder's operation, leads to a more rapid and successful issue, and affords a permanent result, *because the glands, which are the chief pathological factors, are thoroughly removed.* I have no experience with Schroeder's operation, but Emmet's trachelorrhaphy, or some modification of it, has served an excellent purpose in such cases.

The radical extirpation of the gland-tissue becomes more imperative if we accept the view of Ruge and Veit, that there is not only a close relationship between erosions and cancer, but that many cases of cancer may actually be traced to an origin in the gland structure. The process of repair in these erosions confirms this view.

"While in the repair of erosions, in some cases, the cylindrical epithelium transforms itself into squamous epithelium, which, by increase and layering, gradually narrows the gland-outlets more and more, compresses them, as it were cuts them off, so that they persist under the squamous epithelium; on the other hand, instead of this incomplete healing, the squamous epithelium may creep into the glands. Often the upper half of the gland is found already filled. But another process of termination may occur. Frequently everything up to a small piece of gland-tissue, corresponding to its bottom, may be converted into squamous epithelium or into a better-layered, polymorphous, dermoidal epithelium. In short, we obtain in these processes of cure pictures such as we have frequently described in the development of cancer, as beginning of the latter. *A gland in process of cancerous degeneration is not to be distinguished from one in process of cure.* In the cervix an analogous process of cure takes place when an erosion becomes covered by epidermis; *the squamous epithelium which forms in simple ectropium, or in prolapsus with ectropium, often creeps into the gland only on one side in order to fill it gradually*" ("Zeitschr. für Geburtsh. und Gynaek.," 1881, p. 174). The pathological study of cervical diseases which are here presented briefly points to the inevitable conclusion that *the cervical follicles are significant factors in all benign diseases of the cervix uteri.*

The connection between benign and malignant disease of the cervix has already been referred to. It remains now to show more definitely how far *the cervical follicles are significant as elements in the pathology of that most loathsome of all uterine diseases, carcinoma.* I must again draw from that valuable source of information on pathology, the labors of Ruge and Veit, who have examined numerous specimens of carcinomatous tissue, removed, in various stages, by Carl Schroeder and others. The minute descriptions of the mi-

croscopic appearances, which are beautifully illustrated in their work ("Der Krebs der Gebärmutter," "Zeitsch. für Geburtshülfe und Gynækol.," 1881), establish beyond a doubt the correctness of their view that *carcinoma of the cervix originates in the follicles.* "When it develops within the cervix, it arises from the connective tissue or the already present though rankly growing glands, while, when it develops on the portio vaginalis, it takes its origin in the connective tissue or in newly formed glands. Hence both forms have this much in common, although they differ in some other respects: that *a glandular formation serves them as their point of origin*" (pp. 208, 209).

It would probably interest you as deeply as it interested me during the investigation of this momentous question to follow these practical microscopists, who are intimately connected in their work with Berlin's best clinical gynæcologists, in the description of some of the microscopic drawings which they furnish. But I will quote very briefly, in order to impress upon your minds the salient points in connection with my subject, only the concluding summary (p. 169): "First, the squamous epithelium was found sometimes slightly thickened near the end (of the portio); next followed *glandular erosions*, covered with cylindrical epithelium which degenerated into cancer. In many cases in which cancer apparently occurred upon the plain terminations of the squamous epithelium, its development from glands could frequently be demonstrated beyond a doubt. We can say that a large proportion of carcinoma of the portio vaginalis are gland cancers, which receive their origin in newly developed glands (erosions). We therefore still remain upon our former standpoint, that erosions are not always simple and insignificant processes. We are glad (in reply to Scanzoni, who said that the incipient stages of development of cancer were unknown) to say that we have seen early development of cancer, and that we have demonstrated for this category a development from glands."

What lessons are inculcated by the pathological evidences which I have brought before you to prove the paramount influence of the gland structure as a factor in benign as well as in malignant diseases of the cervix uteri? The original intention of my studies on the subject was to demonstrate the urgent necessity of recognizing the gland structure in the operation for lacerated cervix, to show how important the mere repair of the laceration would be in the direction of a cure, and to insist upon the necessity of free, thorough, and unsparing removal of all gland-tissue in this operation. But, as the subject became more and more elaborated in my mind, I was led into the more complete review which is here presented.

Ruge and Veit have told us: "*A gland in process of cancerous degeneration is not to be distinguished from one in process of cure.*" Pregnant words these from the pen of careful observers, reminding us how readily the scale may be turned from a benign to a malignant process.

The microscope has confirmed the conclusions which clinical observation has furnished. Dr. Emmet has long insisted that epithelioma of the cervix was almost invariably connected with a previously existing laceration, having never discovered epithelioma in women who had not at some time been delivered of a fœtus. Breisky, Gusserow, Hofmaier, and others have confirmed Emmet's view to this extent at least, that, in their experience, carcinoma of the cervix is comparatively rare in nulliparous women.

The lesson, therefore, is plain. Lacerations, erosions, and ulcerations, which do not readily respond to ordinary treatment, must be regarded with suspicion as possible sources for the development of malignant disease. When surgical measures are demanded for their repair, the removal of the gland structure is paramount, and should be executed, as vigorously as is done in true malignant disease, by encroaching as far as possible upon the healthy parenchyma of the cervix. This complete extirpation of the gland structure will not only secure a complete cure in benign cases, but prevent the possible development of malignant disease.

Summary.

1. A thorough knowledge of the anatomy, physiology, and pathology of the cervical follicles will simplify the treatment of many uterine affections.

2. The cervix uteri represents a large gland of active and important function in the various sexual relations of woman.

3. In the majority of the more common diseases of the uterus the mucous membrane and its follicles play the most important rôle. A recognition of this fact will make treatment more successful.

4. Metritis, subinvolution, hyperplasia with catarrh, erosions, etc., must be studied in connection with the glands of the cervix.

5. In obstinate cases medicinal applications fail because the secreting surfaces of the follicles are not reached. Scarification and the curette are valuable adjuncts in nulliparous women or in parous women without cervix laceration.

6. In parous women with lacerations, trachelorrhaphy is the most valuable procedure. As a simple plastic operation it will fail. Success depends on extirpation of the follicles, which is more important than "removal of the cicatricial plug."

7. The microscope demonstrates the dependence of catarrh, ulceration, erosion, and hypertrophy of the cervix, and often also of the body of the uterus, upon the glandular structure of the cervix uteri.

8. The cervical follicles are significant as elements in the pathology of cervix cancer, because the microscope demonstrates the dependence of the latter upon erosions, which are based upon the gland structure.

9. Laceration and erosion must be regarded with suspicion, as possible sources of future malignant disease. In operating for their removal, extirpation of the cervical follicles must be unsparing.

Protective Choleraic Inoculation in Spain, under the direction of Dr. Ferrán, the Government prohibition of which has been withdrawn, is to be further prosecuted, as we learn by the "Union médicale," under the observation of a French commission consisting of Professor Brouardel, M. Roux, who is an assistant of Pasteur's, and M. Albarran, the last-named gentleman having been chosen on account of his knowledge of the Spanish language.

The Honorary Degree of LL. D. has been conferred on Dr. Thomas F. Rochester, of Buffalo.

Book Notices.

Lectures on Diseases of the Nervous Sytsem, especially in Women. By S. Weir Mitchell, M. D., Member of the National Academy of Sciencs, Physician to the Orthopædic Hospital and Infirmary for Diseases of the Nervous System, etc. Second Edition, revised and enlarged, with Five Plates. Philadelphia: Lea Brothers & Co., 1885. Pp. 287. [Price, $1.75.]

Dr. Mitchell's numerous admirers will welcome a new edition of his interesting little volume, especially as it contains several fresh pages on the subject of hysteria, on which he always writes so graphically. Chapter XVI, on "The Rectum and Defecation in Hysteria," contains a number of curious and interesting facts concerning this protean disorder. The closing chapter contains a concise statement of the advantages and method of application of the rest-cure, which the talented author has already rendered so famous.

The subject of chorea is carefully treated of, the relation of the disease to locality and meteorological conditions being carefully studied and illustrated by charts. The style is, like that of all of the author's writings, clear and forcible. Aside from its scientific value, the book offers most interesting reading.

Modern Therapeutics of the Diseases of Children, with Observations on the Hygiene of Infancy. By Joseph F. Edwards, M. D., Editor of the "Annals of Hygiene," etc. Philadelphia: D. G. Brinton, 1885. Pp. vii–17 to 346, inclusive.

The author modestly remarks in the preface that "no similar work of anything like this extent has ever been published," a statement calculated to raise the expectations of the reader to a high pitch. Unfortunately, these expectations are not entirely realized. The volume certainly contains a number of valuable suggestions, and will be acceptable to a certain class of readers, but, to tell the truth, there is so much waste matter in it that the true pearls are hard to find. Numbers of the prescriptions which are credited to certain modern physicians have been in use for over a century, and many of the "eminent specialists" whose teachings are quoted are unknown to fame.

The main criticism to be urged against the book is its prolixity. The writer has certainly devoted an immense amount of time to the compilation.

The Year-Book of Treatment for 1884. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia: Lea Brothers & Co., 1885. Pp. 316.

This little volume contains a large amount of useful information within a small space. The names of the contributors are a sufficient guarantee of the accuracy of the work. The paragraphs, although necessarily condensed, are sufficiently full; the references to current literature are carefully given, and show wide research. Although the writers are English, they generously allow a fair amount of space to extracts from American journals. We note, as especially worthy of commendation, the sections on "Diseases of the Stomach, Intestines, and Liver," by Dr. Brunton; on "General Surgery," by Mr. Bryant; and on "Diseases of Women," by Dr. Williams. Mr. Champneys contributes a lengthy chapter on "Midwifery," and Mr. Malcolm Morris an excellent *résumé* of the latest advances in the department of dermatology. There are two carefully prepared indexes, one referring to the authors quoted, the other to diseases. The book is of a size suitable for the pocket, and the type and binding leave nothing to be desired.

Modern Medical Therapeutics: A Compendium of Recent Formulæ and Specific Therapeutical Directions, from the Practice of Eminent Contemporary Physicians, American and Foreign. By George H. Napheys, A. M., M. D., etc. Edited by Joseph F. Edwards, M. D., and D. G. Brinton, M. D. Eighth Edition, Enlarged and Revised. Philadelphia: D. G. Brinton, 1885. Pp. xv–629.

The fact that this work has reached an eighth edition proves that it must be popular with the profession, yet this is not necessarily an argument in favor of its intrinsic excellence. Although we do not regard with much favor the regular practice of borrowing other men's prescriptions, there are undoubtedly useful hints to be derived from a study of the methods of treatment employed by different practitioners. The advantage complacently set forth by the editors, that the present edition has been increased by "more than a hundred pages," will not strike the thoughtful reader as especially great. There is too much irrelevant matter in the book already. The size of the volume is the least of its attractions. While, as we before remarked, we do not become enthusiastic over Dr. Napheys's works, they certainly possess good points, and should not be dismissed without some commendation.

BOOKS AND PAMPHLETS RECEIVED.

On Some Common Injuries to Limbs; their Treatment and After-treatment, including Bone-setting (so called). By Edward Cotterell, M. R. C. S. Eng., L. R. C. P. Lond., etc. With Illustrations. London: H. K. Lewis, 1885. Pp. x–108.

Hay Fever, and its Successful Treatment by Superficial Organic Alteration of the Nasal Mucous Membrane. By Charles E. Sajous, M. D., etc. Illustrated with Thirteen Wood Engravings. Philadelphia: F. A. Davis, Att'y, 1885. Pp. 103.

A Treatise on Practical Chemistry and Qualitative Inorganic Analysis, adapted for Use in the Laboratories of Colleges and Schools. By Frank Clowes, D. Sc. Lond., etc. With Illustrations. From the Fourth English Edition. Philadelphia: Lea Brothers & Co., 1885. Pp. xiv–376.

The Ten Laws of Health; or, How Diseases are produced and prevented: and Family Guide to Protection against Epidemic Diseases and Other Dangerous Infections. By J. R. Black, M. D. Philadelphia: J. B. Lippincott Co., 1885. Pp. xviii–13 to 413, inclusive. [Price, $2.]

The Pathology and Treatment of Stricture of the Urethra and Urinary Fistulæ. By Sir Henry Thompson, F. R. C. S., M. B. Lond., etc. Fourth Edition. Philadelphia: P. Blakiston, Son & Co., 1885. Pp. xii–254. [Price, $2.]

Medical Topics. Containing: 1. Hints and Suggestions for Reform in Medical Education. 2. A Plea for the State Regulation of Medicine and Surgery. 3. Medical Education; its Objects and Requirements. By F. R. Sturgis, M. D., Ex-president of the Medical Society of the County of New York, etc. New York: William Wood & Co., 1885. Pp. 63. [Price, 25c.]

Pneumonia in Young Children. By L. Emmett Holt, A. M., M. D., Attending Physician to the Children's Department of the Northwestern Dispensary, etc. [Reprinted from the "Medical Record."]

Epilepsy. By L. W. Baker, M. D., Superintendent of a Hospital for Epileptic Children, Baldwinsville, Mass. [Reprinted from the "Journal of Nervous and Mental Disease."]

NEW YORK, SATURDAY, JULY 4, 1885.

THE INTERNATIONAL MEDICAL CONGRESS.

In this issue we conclude our report of the Chicago meeting of the American Medical Association's Committee on the International Medical Congress. Several of the members of the original committee were present and took part in the proceedings, a fact that can not be otherwise construed than as a complete recognition on their part—and presumably on the part of the original committee as a body—of the new committee's legitimacy.

The enlarged committee, therefore, with power to fill vacancies occurring even among the original members, now constitutes the only body charged with the organization of the Congress. That being the case, its acts assume an importance that might have been questioned before. We are glad to be able to say that the convictions which we expressed two weeks ago have been justified by the moderation and breadth of view shown at Chicago. Of course, we deplore the fact that the committee was under compulsion to cut off the heads of a number of distinguished men whose co-operation the Congress can ill afford to spare; and it is humiliating to reflect that this compulsion was not the outgrowth of any spontaneous expression of feeling on the part of the profession, but merely the natural sequence of the excitement brought about at New Orleans. It was none the less real and morally binding, however, and we readily concede that the committee, whatever may have been the feelings of its individual members, had no course open to it but the very course that it took. When in the future—and, to judge by the action taken in Philadelphia, in the near future—it comes to be admitted on all hands that an honest difference of opinion as to how far a sentiment should be allowed to sway the policy of the profession ought never to have been magnified into an issue before which every other consideration should be made to yield, and perverted into a test of personal worth, it will certainly be recognized that the responsibility for carrying out those monstrous notions to the extent of wantonly humiliating some of the best men to be found in the ranks of the medical profession, and at the same time detracting from the strength of the home representation at a convocation of the medical men of the whole world, condemnation will not be visited upon this committee, but upon those whose acts called it into existence.

The committee, we repeat, is not to be held chargeable with the crippling of the Congress that must be the result of the foolish policy settled upon at New Orleans—a policy that has already begun to bear its bitter fruit, as shown by the action of our brethren in Philadelphia. The preambles and resolution adopted by them (for a copy of which we are indebted to the courtesy of the "Medical News," of Philadelphia) show plainly that the strong men of the profession in that city are not to be made the cat's paws of a little knot of agitators. It is significant that several of the names signed to the resolution are those of men appointed to high positions in the new list of officers of the Congress.

There was only one other main question with which the committee had to wrestle, and that was the demand for a more strictly geographical representation in the organization of the Congress. So far as the proceedings at New Orleans could be taken as an indication of what was wanted, this demand seemed much more obtrusive than the feeling on the code question. There was danger, consequently, that the committee would feel constrained to take sweeping measures, and to make the officers of the Congress represent not the medical achievements of the country, but its territorial districts. We think an examination of the new list of officers decided upon by the committee will show that, while it has done all that could fairly be expected of it by the most exacting stickler for local representation, it has yet contrived to fill the prominent places with well-known men—men in every way fitted for the positions to which they have been appointed. We must therefore congratulate the committee upon this portion of its work, and we feel convinced that whatever sense of disappointment may be the portion of those whose names have been lopped off from the original list will arise from the thought, not that they as individuals have had an indignity put upon them, but that they are debarred from showing their devotion to American medicine on an occasion when, more than on any other, it would have been conspicuous and effective. While we praise the work of the committee, we must confess that the outlook for the Congress is gloomy.

THE EMBRYOLOGICAL RELATIONS OF CONGENITAL MALFORMATIONS OF THE PHARYNX.

At the fourteenth congress of the German *Gesellschaft für Chirurgie*, an excellent digest of the proceedings of which is published in the form of a supplement to the "Centralblatt für Chirurgie," Dr. Albrecht, of Brussels, read a notable paper on the morphological significance of pharyngeal diverticula. He sought to establish that, besides the lungs, there were two different sorts of these diverticula in the human subject, namely, the dorsal, epipharyngeal, or retropharyngeal, and the lateral or parapharyngeal. The epipharyngeal diverticula of man, he says, are those which Zenker and von Ziemssen have characterized as "impulse-diverticula" (*Pulsionsdivertikel*). In all the cases thus far observed the opening of the larynx, that of the œsophagus, and that of the diverticulum have all been situated at the same level. Since a like diverticulum, the so-called œsophageal cæcum of the veterinarians, is found as a normal structure in several of the *Mammalia* (constantly in the hog, the camel, and the elephant, and occasionally in the ox), Albrecht maintains that Zenker and von Ziemssen's impulse-diverticula in man have the morphological significance of atavistic formations, and are to be referred to the same sources as the œsophageal cæcum, which latter, furthermore, he looks upon as a

homologue of the air-bladder of fishes, having no homology with lungs, since there are certain *Teleosteans* (*Diodon*, *Triodon*, and *Tetrodon*) that have both lungs and air-bladders, while, on the other hand, in some of the *Selachians* (*Galeus*, *Mustelus*, and *Acanthias*) the air-bladder is found to have the form of an epipharyngeal diverticulum. Since in the hog, the œsophageal cæcum (*Rachentasche*) of which was demonstrated with a preparation, the pouch is overlain by the crico-pharyngeus muscle, and its mucous membrane can be inverted beneath the crico-pharyngeus with the finger, thus what is known in man as pharyngocele being produced artificially, we have an explanation of the presence, often recorded in literature, of muscular fibers on the cranial portion of the impulse-diverticulum in man, doubted by Zenker and von Ziemssen on theoretical grounds. The Zenker-von Ziemssen *versus* König controversy in regard to these muscular fibers is therefore decided in König's favor, for the cranial portion of the pouch must, under all circumstances, be covered by the crico-pharyngeus.

In man, the author continues, all the parapharyngeal diverticula have the same morphological significance; they all originate in the second post-oral cleft (bounded by the hyal arch, consisting of the styloid process, the stylo-hyoid ligament, and the lesser cornu of the hyoid bone, and the ventral rudiment of the first branchial arch, the greater cornu of the hyoid bone), the cutaneous opening of which is closed, while the blind termination thus formed is dilated into a pouch. To the same mode of origin we must refer congenital cervical fistulas, and congenital hydroceles, atheromas, and dermoid cysts of the neck. If the second post-oral cleft does not close at all, a congenital cervical fistula is the result; if its cutaneous opening closes, an internal incomplete fistula is formed, which, if its lateral blind end bulges, gives the impression, as in a case cited from Watson, of a lateral diverticulum of the pharynx; if both the cutaneous and the pharyngeal openings close, either a hydrocele, an atheroma, or a dermoid cyst is developed, according as the contents are serous, pultaceous, or containing dermoid formations, such as hair and teeth.

Like congenital fistulas of the neck, the parapharyngeal diverticula lie mediad of the sterno-cleido-mastoid muscle, making their way first between the external and the internal carotid arteries, then between the glosso-pharyngeal nerve and the stylo-pharyngeus muscle, to open finally into the pharynx behind the pharyngo-palatine arch. The reason why the cutaneous orifice of a congenital cervical fistula and the blind end of a pharyngeal diverticulum lie close above the sterno-clavicular joint is to be found in the cranio-caudad migration of the two respectively, a migration which tallies with the caudad migration of the stomach, the heart, and the aortic arch; and the single explanation lies in the fact that, instead of the twenty-first spinal nerve, a cranial nerve goes to the stomach in man, and the inferior laryngeal nerve makes a turn two feet long, in the adult, around the fourth aortic arch (the arch of the aorta on the left, and the innominate artery and the proximal portion of the subclavian on the right side) before reaching the laryngeal muscles to which it is distributed. The author considers that the larynx, the air-passages, and the lungs constitute a normal hypopharyngeal diverticulum.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 30, 1885:

DISEASES.	Week ending June 23.		Week ending June 30.	
	Cases.	Deaths.	Cases.	Deaths.

Scarlet fever	54	7	29	7
Cerebro-spinal meningitis	2	2	1	1
Measles	89	17	100	25
Diphtheria	57	23	63	35

The American Medical Association's Committee on the International Medical Congress.—Chicago, *June 25th.*—The meeting of to-day was called to order by the Chairman, Dr. Cole, at 9.20 A. M. The minutes of yesterday's meeting were read and adopted. Dr. R. Battey offered the following preamble and resolution:

Whereas, It is expedient that the meetings of this committee shall represent, as far as practicable, the profession of all portions of our country,

Resolved, That any member of the committee who may be unable to attend a meeting shall be empowered to send as his proxy for the meeting any member of the American Medical Association in good professional standing, and a resident of his State or member of his Government Department. Adopted unanimously.

Chairman Scott, of the sub-committee appointed yesterday, stated that the secretary would read this committee's report before its adoption, as it had been placed in his hands. Some general remarks were made as to the method of adopting the rules, and it was decided to act on them *seriatim*. The result of this action was that most of the rules reported by the committee were adopted, some amendments being made to a few of them. As they can not be given with exactness until after the committee's final revision, it is thought best not to attempt to incorporate them in this report. It is sufficient to say at present that Rule I was so amended as to guard against the participation of irregular practitioners in the meetings of the Congress.

That portion of the committee's report which had reference to the list of officers for the Congress contained the following nominations: For president, Austin Flint, of New York. For vice-presidents, N. S. Davis, of Chicago; H. F. Campbell, of Augusta, Ga.; R. P. Howard, of Montreal, Canada; T. G. Richardson, of New Orleans; A. Stillé, of Philadelphia; W. O. Baldwin, of Montgomery, Ala.; H. M. Skillman, of Lexington, Ky.; L. A. Sayre, of New York; W. W. Dawson, of Cincinnati; J. M. Toner, of Washington; W. Brodie, of Detroit; J. L. Atlee, of Lancaster, Pa.; and O. W. Holmes, of Boston. For secretary-general, John Packard, of Philadelphia. For chairman of the Finance Committee, F. S. Dennis, of New York. For members of the Committee of Arrangements (those whose names are printed in italics being also members of the executive sub-committee):

George A. Ketchum, Mobile; D. A. Linthicum, Helena, Ark.; *R. B. Cole* (chairman), San Francisco; Charles Denison, Denver, Col.; W. C. Wile, Sandy Hook, Conn.; W. E. Duncan, Dakota Territory; L. P. Bush, Wilmington, Del.; *A. Y. P. Garnett*, Washington; R. D. Murray, Moultrie, Pa.; Robert Battey, Rome, Ga.; E. P. Cook, Mendota, Ill.; F. W.

Beard, Vincennes, Ind.; W. Watson, Dubuque, Iowa; D. W. Stormont, Topeka, Kan.; W. H. Wathen, Louisville; J. W. Dupree, Baton Rouge; S. C. Gordon, Portland, Me.; *J. S. Lynch* (vice-chairman), Baltimore; A. H. Wilson, South Boston, Mass.; A. R. Smart, Hudson, Mich.; George F. French, Minneapolis; J. M. Taylor, Corinth, Miss.; N. F. Essig, Plattsburg, Mo.; R. C. Moore, Omaha; J. W. Parsons, Portsmouth, N. H.; William Pierson, Orange, N. J.; Ellsworth Eliot, New York; X. C. Scott, Cleveland; E. P. Fraser, Portland, Oregon; *J. V. Shoemaker* (secretary), Philadelphia; W. E. Anthony, Providence; R. A. Kinloch, Charleston; F. L. Sim, Memphis; J. W. McLaughlin, Austin; E. T. Upham, West Randolph, Vt.; W. C. Dabney, Charlottesville, Va.; G. Baird, Wheeling, W. Va.; Nicholas Senn, Milwaukee; J. J. McAchran, Laramie City, Wyoming Territory; J. B. Hamilton, Washington; Robert Murray, U. S. Army, Washington; F. M. Gunnell, U. S. Navy, Washington; *W. Pierson;* J. S. Billings, U. S. Army; J. M. Brown, U. S. Navy; I. M. Hays, Philadelphia; H. F. Campbell, Augusta, Ga.; *C. Johnston*, Baltimore; *J. W. S. Gouley*, New York; L. A. Sayre, New York; G. J. Engelmann, St. Louis; *F. S. Dennis*, New York; and *J. Packard*, Philadelphia. For Local Committee of Arrangements: A. Y. P. Garnett (chairman), J. S. Billings, S. O. Ritchie, and Frank Baker, all of Washington, with power to add to their number any of the physicians of Washington in good standing. For officers of sections: SECTION I (*Medical Education, Legislation, and Registration*).—President, S. E. Chaillé, New Orleans. Vice-presidents: G. Capples, San Antonio, Tex.; R. J. Dunglison, Philadelphia. Secretaries: E. F. Dunbar, Boston; Trail Green, Easton, Pa. Council: H. D. Didama, Syracuse, N. Y.; D. C. Gilman, Baltimore; J. F. Harrison, University of Virginia; C. A. Lindsley, New Haven; W. Pepper, Philadelphia; J. F. Prioleau, Charleston; L. McL. Tiffany, Baltimore; H. Gibbons, San Francisco; J. A. Dibbrell, Jr., Little Rock, Ark.; C. L. Allen, Rutland, Vt.; H. O. Hitchcock, Kalamazoo, Mich.; R. H. Reed, Mansfield, O.; J. W. Bailey, Gainesville, Ga.; K. Wylie, Sanford, Fla. SECTION II (*Anatomy*).—President, J. Leidy, Philadelphia. Vice-presidents: W. Pancoast, Philadelphia; C. W. Kelley, Louisville; S. Logan, New Orleans. Secretaries: W. W. Keen, Philadelphia; G. E. de Schweinitz, Philadelphia. Council: H. Allen, Philadelphia; F. Baker, Washington; A. Henson, Philadelphia; T. Dwight, Boston; F. L. Parker, Charleston; C. T. Parkes, Chicago; T. T. Sabine, New York; N. Senn, Milwaukee; J. F. Shepherd, Montreal; R. W. Shufeldt, U. S. Army; G. Halley, Kansas City; S. W. Craft, Jackson, Miss. SECTION III (*Physiology*).—President: J. C. Dalton, New York. Vice-presidents: H. P. Bowditch, Boston; J. F. Hibberd, Richmond, Ind.; H. N. Martin, Baltimore; M. Michel, Charleston. Secretary: J. G. Curtis, New York. Council: G. Baumgarten, St. Louis; H. G. Beyer, U. S. Navy; A. Flint, Jr., New York; W. Lee, Washington; J. J. Mason, Newport, R. I.; H. Sewall, Ann Arbor, Mich.; W. F. Hyer, Holly Springs, Mich.; J. H. Wyeth, San Francisco; A. D. Brubaker, Philadelphia; A. F. Whelan, Hillsdale, Mich.; T. S. Latimer, Baltimore; S. Putnam, Montpelier, Vt.; C. H. A. Kleinschmidt, Washington. SECTION IV (*Pathology*).—President: F. Delafield, New York. Vice-president: W. Pepper, Philadelphia. Secretaries: H. M. Briggs, New York; W. H. Welch, Baltimore; I. N. Himes, Cleveland. Council: C. Fenger, Chicago; R. H. Fitz, Boston; E. G. Janeway, New York; J. B. Johnson, St. Louis; G. M. Sternberg, U. S. Army; W. F. Whitney, Boston; C. H. Hunter, Minneapolis; E. O. Shakespeare, Philadelphia; H. Schmidt, New Orleans; M. Longstreth, Philadelphia. SECTION V (*Medicine—including the original section in Nervous Diseases and Psychiatry.*—President: J. M. DaCosta, Philadelphia. Vice-presidents: Alonzo Clark, New York; J. B. McCaw, Richmond; C. F. Folsom, Boston; J. P. Gray, Utica, N. Y.; J. S. Jewell, Chicago; R. McSherry, Baltimore; A. B. Palmer, Ann Arbor, Mich.; T. F. Rochester, Buffalo; S. W. Mitchell, Philadelphia; P. G. Robinson, St. Paul. Secretaries: W. Osler, Philadelphia; J. T. Whittaker, Cincinnati; W. Hay, Chicago. Council: R. Bartholow, Philadelphia; F. T. Miles, Baltimore; S. G. Webber, Boston; J. P. Logan, Atlanta; F. B. Lester, Kansas City; A. B. Arnold, Baltimore; E. D. Ferguson, Troy, N. Y.; S. C. Chew, Baltimore; W. H. Geddings, Aiken, S. C.; W. W. Johnston, Washington; G. A. Ketchum, Mobile; F. Minot, Boston; B. Robinson, New York; J. Burnett, Cleveland; W. W. Cleaver, Lebanon, Ky.; W. H. Phillips, Canton, O.; S. S. Clark, St. Albans, Vt.; G. Williamson, Ottawa, Canada; J. Draper, Brattleboro, Vt.; E. Grissom, Raleigh, N. C.; P. Brice, Tuscaloosa, Ala. SECTION VI (*Surgery*).—President: D. W. Yandell, Louisville. Vice-presidents: D. H. Agnew, Philadelphia; W. T. Briggs, Nashville; S. W. Gross, Philadelphia; W. H. Hingston, Montreal; R. A. Kinloch, Charleston; E. M. Moore, Rochester; M. Gunn, Chicago. Secretaries: J. C. Warren, Boston; D. P. Allen, Cleveland. Council: J. Ashhurst, Jr., Philadelphia; D. W. Cheever, Boston; P. S. Conner, Cincinnati; G. E. Fenwick, Montreal; F. H. Gerrish, Portland, Me.; J. C. Hutchison, Brooklyn; C. Johnston, Baltimore; T. M. Markoe, New York; A. P. Smith, Baltimore; J. F. Thompson, Washington; T. R. Varick, Jersey City; H. H. Mudd, St. Louis; J. R. Weist, Richmond, Ind.; J. P. Wall, Tampa, Fla.; —— Mercer, Omaha; H. Bingham, Burlington, Vt.; T. A. Dunsmore, Minneapolis; J. T. Carpenter, Pottsville, Pa.; W. S. Janney, Philadelphia; J. Garland, Boston; —— Crompton, Lancaster, Pa. Section XVI (*Diseases of Children*).—President: J. L. Smith, New York. Vice-presidents: D. Miller, Chicago; S. C. Busey, Washington. Secretary: E. T. Williams, Boston. Council: F. Forchheimer, Cincinnati; J. M. Keating, Philadelphia; W. Lee, Baltimore; J. H. Pope, Marshall, Tex.; W. B. Atkinson, Philadelphia; A. Walker, Evansville, Ind.; W. A. Conklin, Dayton, O.; W. F. Holt, Macon, Ga.; K. Johnson, Grand Rapids, Mich.; C. A. Leale, New York; S. H. Charlton, Seymour, Ind.; W. H. Dougherty, Augusta, Ga.; B. H. Riggs, Selma, Ala.; H. H. Middlekamp, Ironton, Mo.; J. A. Hodge, Henderson, Ky.; G. W. Moody, Huron, Dakota T.; A. A. Horner, Helena, Ark.

Dr. W. H. Watnen offered the following preamble and resolution: .

Whereas, It has become necessary, in order that this committee may fully understand the professional and personal standing of the various persons suggested for appointment, therefore be it

Resolved, That it is the sense of this meeting that all remarks bearing upon the qualifications of said persons be considered as strictly confidential between the members of the committee, and that the report of such remarks, if heretofore recorded, be expunged from the minutes. Carried unanimously.

The committee then adjourned, to meet in St. Louis on the Monday preceding the next meeting of the American Medical Association.

New York State Medical Association, Northern Branch.—The first annual meeting will be held in Utica on Tuesday, the 7th instant. The following papers are expected to be read: "Well-water and its Uses," by Dr. Malek A. Southworth, Little Falls; "The Treatment of Hæmorrhoids by Recent Methods and Instruments," by Dr. Leroy J. Brooks, Norwich; "Extra-uterine Pregnancy," by Dr. William A. Hall, Fulton; "Ankylosis of the Knee Joint as a Remedy for Extreme Paralysis of the Leg, due to Infantile Paralysis," by Dr. Stephen Smith, New York; "The Advantages of Paris as a Place of Medical Education," by Dr. M. M. Bagg, Utica; "Jaborandi and its Uses in Typhoid Fever," by Dr. Wallace Clarke, Utica.

The District Medical Society for the County of Hudson, N. J., will meet at the Stevens Institute, in Hoboken, on Tuesday, the 7th inst., at 3 o'clock P. M. Dr. W. P. Watson will read a paper on Cholera Infantum, and Dr. J. Lewis Smith and Dr. J. H. Ripley, of New York, are expected to take part in the discussion.

The International Medical Congress and the Medical Profession of Philadelphia.—A meeting of the members of the medical profession of Philadelphia concerned in the organization of the International Medical Congress of 1887 was held at the Hall of the College of Physicians, on Monday, June 29th, Dr. Alfred Stillé in the Chair. Dr. David W. Yandell, of Louisville, was present by invitation.

After hearing a report of the proceedings of the new committee, at the meeting held in Chicago last week, and, after considering the changes in the organization which were made, including the restriction of the scope of the membership, by which a large proportion of the profession of the country would be excluded from the Congress, the following preambles and resolution were unanimously adopted:

Whereas, Certain serious changes have been recently effected in the preliminary organization and rules for the International Medical Congress of 1887, it has seemed desirable for the members of the General Committee and the officers of the Sections resident in Philadelphia to meet for consultation; and

Whereas, It has appeared that these changes are inconsistent with the original plan, and detrimental to the interests of the medical profession in America, and of the International Medical Congress; therefore be it

Resolved, That we, the undersigned, consider that our duty to the profession and to ourselves requires us to decline to hold any office whatsoever in connection with the said Congress as now proposed to be organized:

D. Hayes Agnew,
Roberts Bartholow,
John H. Brinton,
Charles H. Burnett,

David W. Yandell.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 21, 1885, to June 27, 1885:*

Hartsuff, Albert, Major and Surgeon. Assigned to duty at Fort Hamilton, New York Harbor. S. O. 133, Department of the East, June 24, 1885.

Middleton, J. V. D., Major and Surgeon. Granted one month's leave, with permission to apply for fifteen days' extension, to take effect about the 15th proximo. S. O. 88, Department of the Missouri, June 19, 1885.

Brown, H. E., Major and Surgeon. Assigned to duty as post surgeon, Fort Reno, Indian Territory. S. O. 91, Department of the Missouri, June 24, 1885.

Taylor, Blair D., Captain and Assistant Surgeon. Ordered from Department of Texas to Department of the East. S. O. 141, A. G. O., June 20, 1885.

Caster, William F., Captain and Assistant Surgeon. Ordered from Department of the East to Department of Texas. S. O. 141, A. G. O., June 20, 1885.

Davis, William B., Captain and Assistant Surgeon. Leave of absence extended three months. S. O. 142, A. G. O., June 23, 1885.

Ebert, R. G., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect about July 5th. S. O. 97, Department of the Columbia, June 17, 1885.

Robertson, R. L., First Lieutenant and Assistant Surgeon. Now on leave of absence, directed to report in person by July 7, 1885, to commanding officer, Columbus Barracks, Ohio, to accompany detachment of recruits to Department of Texas. On completion of this duty, to rejoin his proper station. S. O. 143, A. G. O., June 24, 1885.

Society Meetings for the Coming Week:

Monday, *July 6th:* New York Academy of Sciences (Section in Biology); Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford City, Conn., Medical Association; Chicago Medical Society.

Tuesday, *July 7th:* Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Medical Society of the County of Broome, N. Y.; Ogdensburg, N. Y., Medical Association; Hudson County (Jersey City) and Union County (quarterly), N. J., Medical Societies; Chittenden County, Vt., Medical Society; Androscoggin County, Me., Medical Association (Lewiston).

Wednesday, *July 8th:* American Microscopical Society of the City of New York; Medical Societies of the Counties of Cayuga and Seneca (annual). N. Y.; Tri-States Medical Association (Port Jervis, N. Y.); Franklin District (quarterly—Greenfield), Hampshire District (quarterly—Northampton), and Worcester District, Mass. (Worcester), Medical Societies.

Thursday, *July 9th:* Brooklyn Pathological Society; Medical Society of the County of Fulton, N. Y. (semi-annual—Johnstown); South Boston, Mass., Medical Club (private).

Friday, *July 10th:* Medical Society of the Town of Saugerties, N. Y.

Saturday, *July 11th:* Worcester North District, Mass., Medical Society.

Proceedings of Societies.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of June 3, 1885.

A Plea for the Medicinal Use of Pure Alcohol and Alcoholic Mixtures of Known Composition in Preference to Ordinary Fermented Liquids.—Dr. Henry Leffmann read the following paper:

I present to the College this evening, with some misgivings, I confess, a topic which can scarcely yet be considered a "live issue" in clinical medicine, but which is destined, I am certain, to become one. At the present time the profession does not take kindly to suggestions having in view material modifications of its policy in reference to alcoholic liquors. The majority of physicians regard those who preach or practice total abstinence, or throw doubt on the indispensability of alcohol as a therapeutic agent, as entitled to little respect or tolerance. In presenting the view that we should abandon in clinical medicine the use of the natural wines and liquors, and resort to mixtures confessedly fictitious, we must expect to encounter all the force of the conservative spirit. Many centuries of constant use have developed in the race a feeling that fermented drinks, particularly those that, like wines and malt liquors, have suffered no modification by distillation or admixture, are bounties of nature wisely given for our use. The traditions of the past associate the first preparation of liquor with the gods, and in all ages poetry and prose have combined to increase the reverence for these natural products. Yet all this feeling is nothing but a superstition. Fermentation is now known to be a process occurring under the influence of micro-organisms, and it allies itself with ordinary putrefaction. The reverence which we have for "Nature's laboratory" is born of ignorance, and

there is no progress in chemistry more gratifying in its results than that which deals with dispelling the illusions which have surrounded its application to medicine.

Whatever ulterior relations the plan advocated here may have to the questions of total abstinence are not presented for discussion; I merely offer it as a contribution to the methods of exactness and certainty in clinical work.

In the medicinal and dietetic use of fermented liquors, it is the effect of the ethyl alcohol which is sought to be obtained. It is true that those who prescribe liquors a great deal are in the habit of saying that the accessory ingredients, compound ethers, astringents, or bitter principles, etc., are also efficacious, but that, if we closely observe the customs of such prescribers, it will be found not only that the effect expected from the alcohol outweighs that to be obtained from any other ingredient, but also that, in the majority of cases, the accessory ingredients are either not known or recognized.

Taking this fact, then, as a starting point, that an agent universally recognized as one of powerful physiological activity should be used only in the most definite condition. The forms of fermented liquors are numerous, and each form is subject to minor variations, depending on locality and season. The demand exceeds the supply, and hence the strong temptation to dilute and substitute. Within the past few months further notice has been given of the communications by American consuls abroad to the effect that the wines and brandies exported from France and Portugal are fictitious articles, in the majority of cases, and it needs but a little inquiry to show that a very large trade in liquors more or less spurious is carried on over the entire world.

Chemical analysis still has much to accomplish in the study of fermented liquors, but enough is known to enable us to imitate their essential features. The tabular statement of composition gives us a long list of mineral ingredients, but we are reasonably certain that, besides the ethyl alcohol, the only ingredients that need attention are the traces of fusel oil, compound ethers, astringent and bitter principles, and the effect even of their accessories is often more on the mind than on the body.

I suggest first, then, that in all cases in which the general physiological effect of ethyl alcohol is desired, it should be given by prescription, in the form of a rectified spirit of standard strength. My friend, Dr. A. W. Miller, who is familiar with this topic, both from the point of view of the pharmacist and physician, has suggested that such a standard, pure spirit be made officinal under the title *spiritus maydis rectificatus*. Such a suggestion is in the interest of clinical accuracy and safety to the patient. If the medical profession have any concern in the protection of the health and morals of the community—and it would certainly appear that it has great concern—no better opportunity is offered for good work than in reforming the widespread errors in reference to the use of alcoholic liquors. Where is the physician who would say to a patient, Take a little landanum or chloral every day, and leave to the patient or the druggist the duty of determining the dose, or the duration of the treatment? Yet every day physicians give similar recommendations in regard to liquors. The use of rectified spirits in prescriptions is to be recommended on the same ground that we give potassium bromide and iodide in accurate dosage, instead of the sea-water which contains them, or morphine and quinine instead of opium and Peruvian bark. Incidental to the therapeutic accuracy and moral safety which are involved in such practice is the not unimportant question of cheapness. Many liquors command prices far above the actual commercial value of the ingredients they contain. A pure French brandy, for instance, costs twelve dollars a gallon. Its place can be taken by a spirit of much less cost.

Several objections may be made to the plan of using the plain spirit. I can not stop to consider the one which arises from a belief in the superiority of a natural product, from a view that that which arises from a natural process will be necessarily superior to anything artificial; this, as I have said before, is a superstition; but there are some suggestions which are really important. It may be that the accessory ingredients have some therapeutic value, and it has been said to me that while pure alcohol may easily be used during acute disease and in hospital practice, that in long-continued treatment, and as a dietetic, patients can not be made to take it. In these cases the method to be pursued is plain. Let the alcohol be mixed with suitable accessory ingredients. If a combination of bitter tonic, sedative, and stimulant is wanted, it can be prescribed, and so on. There need be no difficulty in the matter, because modern art in the preparation of fictitious liquors has reached such perfection that excellent imitations of the natural liquors are made, and these have the advantage of definite and known composition and greater cheapness.

It is not uninteresting to note here the general nature of this work. I have the samples to illustrate it. In the preparation of fictitious liquors three methods may be employed. 1. The genuine liquor may be diluted with a suitable strength of pure spirit. This will give us a liquor differing but little from the original. 2. The liquor may be imitated by adding to pure spirit coloring and flavoring ingredients. In many cases this will give a liquor substantially identical with the original. 3. The liquor may be made up weak, and then taste and appearance of alcoholic strength be given by means of pepper and bead oil. The latter method is reprehensible, but the two former methods are, I hold, not injurious, and should be recognized.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of June 4, 1885.

The President, Dr. B. F. Baer, in the Chair;
Dr. W. H. H. Githens, Secretary.

Biniodide of Mercury as a Disinfectant in Obstetrics.—Dr. E. P. Bernardy read a paper with this title. His attention had first been called to the use of the biniodide of mercury as a germicide by Dr. Miquel, who had published in "L'Annuaire météorologique de Montsouris" the results of some experiments made to determine the minimum amount of a disinfectant necessary to prevent fermentation in a litre of sterilized beef-broth. His experiments showed that the mercurials were the best antiseptics, the biniodide being nearly three times as strong as the bichloride. In his table of disinfectants he placed the bichloride fourth on the list. To a litre of sterilized beef-broth he found it required 0·025 gramme of the biniodide of mercury to keep the broth pure, while 0·070 gramme of the bichloride of mercury was necessary to produce like effects. This showed that bacterial life was impossible in a solution of one forty-thousandth part of the biniodide, while of the bichloride it required one fourteen-thousandth part. The reader had been so forcibly impressed with these experiments that he had determined to give the biniodide of mercury a trial in obstetric cases where it was necessary to use an antiseptic. The following were the cases in which it had been used:

Case I.—On February 7, 1885, he was requested to take charge of Mrs. D., who had been confined about six weeks previously. It had been her second confinement, the duration of labor had been short and delivery natural, but an extensive laceration of the perinæum had occurred. No attempt had been made to bring the parts together by sutures. On the third evening she had been at-

tacked with severe frontal headache and chills, followed by fever, with great tenderness over the region of the uterus. There being no improvement in her condition, her medical attendant was discharged, and another called in, who gave such an unfavorable prognosis that he also was requested to cease his attendance. The patient had well-marked symptoms of septic poisoning. The pulse ranged from 130 to 140, was small and thready, and disappeared under the pressure of the finger; the temperature was 104° to 105°. She was slightly delirious, and had constant vomiting; the abdomen was swollen and excessively tender; the uterus was enlarged, extending fully three inches above the pubes. In the right side there seemed to be a growth extending up into the abdomen, tender on pressure. On making a vaginal examination, the os was found dilated so that the index-finger could readily enter the uterus. Its withdrawal was followed by a gush of highly offensive matter. The uterus was surrounded by organized lymph, and was immovable. The mass on the right side was easily detected, and was continuous with the lymph surrounding the uterus. The vagina was hot. The perinæum was torn to the anus; the surface was raw and discharged an acrid matter which scalded the surrounding parts. The urine was dark, and, on standing, deposited a reddish material which looked like blood-corpuscles. Dr. A. E. Russell examined the specimen and reported it to be slightly acid, with no albumin or sugar; under the microscope occasional pus-corpuscles were seen, and it was swarming with bacteria. In conjunction with internal treatment, intra-uterine injections were made three or four times a day. A solution of bichloride of mercury, 1 to 2,000, was first used. This was continued for three days without any marked results. The discharges continued as offensive as before. On the fourth day the bichloride was replaced by a 1-to-4,000 solution of biniodide of mercury. Within twenty-four hours an amelioration of all symptoms took place, the pulse fell to 100, and the temperature to 101°; the urine became clear and the discharge odorless. The injections were continued for ten days, their frequency being gradually reduced. The uterus returned to almost its normal size, and the lymph was gradually absorbed. The patient recovered.

Case II.—March 19, 1885, he was called to attend Mrs. W. in her first confinement. On his arrival, he found she had been in labor several hours. Examination showed the os perfectly dilated and the bag of waters protruding. The presentation was of the vertex, in the first position, and he ruptured the amnion. The vagina near its outlet was roughened with venereal warts, and they spread also over the vulva. Labor progressed rapidly and the second stage was happily ended. After waiting nearly an hour, making pressure on the uterus, he made slight traction on the cord, and, while doing so, felt, with his hand upon the uterus, a cup-like depression of the fundus take place. This convinced him that he had an adherent placenta to deal with, and that it would be folly to wait any longer. On introducing the hand he found the placenta completely adherent, so that it could hardly be said which was uterus and which placenta. After considerable trouble, he at last succeeded in detaching the placenta; it took fully three quarters of an hour. On making a second examination, to ascertain if the whole had been removed, his hand came in content with long shreds hanging from all sides of the uterus; the more he scraped, the more there seemed to be. He gave the patient two drachms of fluid extract of ergot. She did well for two days, when toward evening she complained of a chill and severe frontal headache. He then gave her ten grains of sulphate of quinine, with a quarter of a grain of sulphate of morphine, at one dose, and washed out the uterus with a 1-to-4,000 solution of biniodide of mercury. The pulse was 115 and the temperature 102°. The discharge was highly offensive. The injections were repeated every four hours. On the evening of the next day the pulse was 98, the temperature 100°, the discharge odorless, and the patient was perfectly well in ten days more.

Case III.—April 23, 1885, he was requested to call at once to see Mrs. K., who was reported in imminent danger of death. This was her ninth confinement. The history of the previous ones, with one exception, was not good. Her labors had been natural, but followed by terrible flooding and protracted convalescence. He found her in an attack of puerperal convulsions. He gave at once thirty grains of bromide of potassium and twenty of chloral hydrate. This dose was repeated in half an hour; ten minutes later another convulsion occurred. He then bled the patient freely. The os uteri was somewhat enlarged, the cervix soft and dilatable; there was a vertex presentation. Dr. Curtin, whom he had sent for, having confirmed his opinion, and considering that the patient's time was quite up, it was decided to etherize her, dilate the cervix, and deliver. The forceps was applied, and traction made at intervals. A living child was safely extracted. Continuous pressure was maintained over the uterus, but, after the expulsion of the placenta, the organ did not contract until it had been washed out with hot water. The bromide and chloral were continued every two hours, and no more convulsions occurred. The patient did well up to the fourth day, when the discharges became very offensive and the pulse accelerated, and slight tenderness existed over the uterus; but there was no chill or fever. The uterus was thoroughly washed out with a solution of biniodide of mercury, 1 to 4,000, and within twenty-four hours the discharge had become odorless and the tenderness over the uterus had disappeared. The patient recovered after a tedious convalescence.

In these cases it would be seen that the biniodide was prompt in its action, markedly so in Case I, where the bichloride and the biniodide were both employed, the result being decidedly in favor of the biniodide. Naturally, it would be said, here were only three cases from which deductions were to be drawn, and it was only after it had been carefully used in a large number of cases that its efficacy could be proved. It was for this reason that he brought it to the attention of the members of this society, who were in a position to give it a fair and impartial trial, and at some future time give the results of their investigations. He had found the 1-to-4,000 solution of the biniodide non-irritating, and had used it extensively in his gynæcological practice and in washing out pus cavities with good results. In it we had a preparation in which the smallest amount of drug was used with results far exceeding those of any other antiseptic. On account of the small quantity of mercury, there would be less chance of salivation. The method he had pursued in making the solution was: Take three grains and a half of the salt, well triturated in a mortar and rubbed, with one quart of boiling water, slowly added, giving a solution of 1 to 4,390. Since writing the foregoing he had seen in the "Philadelphia Medical Times" for May 16th that Dr. Panas, eye surgeon of the Hôtel-Dieu, used the 1-to-25,000 solution of biniodide of mercury in eye cases. He made the following statements: "After a number of experiments, I have convinced myself that a solution in water, 1 to 10,000, of the bichloride, or a similar solution, 1 to 25,000, of the biniodide of mercury, is much superior to any other antiseptic solution employed in eye surgery.' Here again we had a statement that the biniodide in a smaller quantity was as good an antiseptic as the bichloride.

Dr. Montgomery's experience had led him to the conclusion that the bichloride of mercury was far more effective as a disinfectant than carbolic acid. Its introduction into the Philadelphia Hospital had been due to Dr. Parvin, who had found it very satisfactory. In eighteen cases of puerperal fever that were treated with bichloride injections, only three deaths occurred. This success was attributed by the hospital staff to the use of the bichloride. In private practice the speaker followed the plan of Dr. Garrigues, of New York, and avoided intra-uterine injections after labor, but applied pledgets wet with a bichloride solution over the vulva, after carefully cleansing away clots and washing the external parts with a similar solution. In his last term at the Philadelphia Hospital he had had only two cases of puerperal fever, one of which commenced twelve days after delivery. The history of Dr. Bernardy's cases showed an equal if not better antiseptic power in the biniodide of mercury.

Dr. J. V. Kelly some years ago had had several fatal cases of puerperal fever, and about twenty-five patients that got well.

The trouble commenced in a case of abortion, in which he did not succeed in removing all of the placenta. He was at the same time attending a bad case of erysipelas, and at that time the relationship of puerperal fever and erysipelas was not known to him. He was on the point of giving up his practice and leaving the town, and he consulted Dr. Goodell on that question. Dr. Goodell discountenanced such action, but advised him, when attending an obstetric case, to remove his coat and roll up his sleeves, and wash his hands and arms well with turpentine, using the nail-brush thoroughly. Since that time he had washed his hands in turpentine every day and again before every case of labor. He also used a wash of vinegar or carbolic acid solution before touching a puerperal patient. He had met with no puerperal fever or other septicæmic symptoms since that time.

Dr. Parvin said that, as reference had been made to his having used corrosive-sublimate vaginal injections in the cases of puerperal septicæmia under his care in the Philadelphia Hospital last year, he would refer to the antiseptic treatment in the cases occurring the present year. When he took charge of the obstetrical ward, on the 1st of January, he found five recent cases of septicæmia: two of these patients died; one of the two had apparently recovered and then was attacked by pneumonia —quite possibly this pneumonia had a septic origin. Then there were at least seven other cases, but all these patients, as well as three of the original five, recovered. Injections of a solution of corrosive sublimate, 1 to 5,000, were used in all cases immediately after labor. The external parts were washed, too, with a similar solution. This injection was repeated twice a day in all cases for the first week after labor, while it was used oftener in those having septicæmia. Intra-uterine injections were used only when vaginal injections failed to correct the offensiveness of the discharge, but, as was well known, there might be serious, even fatal, cases of septic disease though the lochial flow was not at all offensive. In private practice, after once washing out the vagina thoroughly with the antiseptic solution immediately after labor, this need not be repeated unless symptoms demanded it, but the bathing of the vulva twice a day with the solution ought not to be omitted. Add, if preferred, to this treatment the use of antiseptic napkins, a practice pursued by Dr. Montgomery at the Philadelphia Hospital so successfully, and he thought we had taken the most important means to guard against the entrance of septic germs after labor. He had had no experience with the biniodide of mercury, and did not know that it would supersede the bichloride. The argument in its favor was as strong as three successful cases could make it, but these were entirely too few, as Dr. Bernardy had justly said, to prove its value and its superiority. In one of the doctor's cases labor was induced, apparently on account of eclampsia. Now, was this the best treatment? Obstetricians were by no means agreed, some of the best condemning such treatment.

Dr. Montgomery used the bichloride solution as an external wash only, not as an injection. He thought the records of the hospitals in which injections were used would not show such good results as those in which they were omitted, if septicæmia was not present.

Dr. Willard had a warning to sound with regard to the use of strong bichloride solutions. He had been using washes and antiseptic dressings made with a 1-to-1,000 solution of bichloride, but, in consequence of what had been written about the advantages of stronger solutions, he had increased the strength to 1 to 500, and within twenty-four hours the stools contained bloody mucus, and were small and griping; there was vesication about the wound and around the limb under the dressings. Entirely dry dressings had been used, but they had been moistened by pus and serum from the wound. He did not see the advantage of solutions in serum so strong as 1 to 100 or 75. Serum was a decomposable substance, and an uncertain portion of the antiseptic agent was destroyed by it. Weak solutions in boiling water seemed more reasonable, and answered every purpose.

Dr. Longaker would like to hear how Dr. Bernardy removed the placenta in the case of adhesion narrated by him. He had been using Credé's method with great satisfaction. He thought the hand should be kept out of the parturient canal as much as possible. He did not use vaginal injections after labor, but depended upon outside washes. He found that the temperature rarely rose during the puerperal period, even after instrumental delivery. He thought care during the third stage would avoid the necessity for antiseptics.

Dr. Parish agreed with Dr. Parvin's views. He had found a solution of 1 to 1,000 of bichloride irritating, and he now used one of 1 to 2,000 or 5,000. Strong solutions caused an appearance resembling erysipelas or inflammation of the derma. Injections were not necessary in every case. Where the surroundings were cleanly and the patient was a multipara he did not use them; but in primiparæ, with contusions or lacerations, and when version or instruments had been employed, he was in the habit of injecting a weak solution of bichloride immediately after delivery. He did not repeat it, but simply washed out the vagina. Cleanliness of hands, instruments, and nurse was the most important point. He had never had any trouble in private practice.

Dr. Bernardy, in closing the discussion, remarked that he thought he had a far better antiseptic in biniodide than the bichloride. He had used the former in surgical cases also, for washing out pus cavities, and always with good results. He did not use intra-uterine washes in every case of labor. He had attended, since the first of the year, about seventy cases of labor, and he had employed the intra-uterine injections in only the three cases detailed. In every case of labor he used carbolic-acid soap on his hands and arms and the external genitalia of the patient. The eclamptic patient had reached or passed her full term, and there was no reason why the child should not be removed. In the case of adherent placenta it was pecled off forcibly and a shreddy lining was left in the uterus, as no line of separation had formed. He believed the dangers consequent on passing the hand and arm into the uterus and vagina were much exaggerated, and he did not hesitate to do so when the exigencies of the case demanded it.

(*To be concluded.*)

NEW YORK OBSTETRICAL SOCIETY.

Meeting of January 20, 1885.

Dr. W. M. Chamberlain Chairman *pro tem.*

A Spiral Tenaculum was presented by Dr. James B. Hunter, who had found it especially useful in operations for fistulæ within the vagina and for repairing the perinæum and cervix uteri. The instrument retained its grasp upon the tissues more firmly than the ordinary tenaculum, and was easily engaged and disengaged.

A Soft-Rubber Female Catheter was also presented by Dr. Hunter. The opening was at the extremity of the tube, and the walls gradually increased in thickness toward one end. He had known nurses to set up a urethritis or cystitis by the use of rigid catheters after minor operations, which was more troublesome than the original disease. He never employed the silver catheter, because of the danger of the mucous membrane becoming engaged in the orifice and being injured.

The Chairman thought the spiral tenaculum might enable

us to avoid hacking the tissues, which sometimes took place when the ordinary tenaculum failed to retain its grasp. With regard to the rubber catheter, he asked if it would not in some cases be too soft.

Dr. HUNTER said that when a firmer instrument was required the ordinary rubber male catheter could be used.

Removal of the Ovaries and Tubes for Extreme Dysmenorrhœa and Mania.—Dr. B. F. DAWSON presented the Fallopian tubes and ovaries removed two days before from a patient with the following history: She was thirty-six years of age, from New Jersey, had been suffering from apparently hysterical symptoms for two years, and from dysmenorrhœa, which became more aggravated at each return of the menstrual flow. Dr. Dawson first saw her eighteen months ago, but was unable to make a satisfactory examination of the pelvic organs because of hyperæsthesia and symptoms of hysteria. Two months afterward he made another examination, and found tenderness over the region of both ovaries, but the patient's condition was still such as to forbid a thorough exploration of the pelvic organs. She then passed into the hands of a physician prominent in the treatment of nervous diseases, who stated that her symptoms were due to simple hysteria and nervous disturbance. But she grew worse, and became the subject of marked convulsive seizures, and two months ago was advised to come to New York for further examination and treatment for disease of the sexual organs. December 29th her physician, Dr. Allen, wrote Dr. Dawson that she was in one of her periodical attacks, and had for four days been lying in a maniacal state. He advised that an operation be performed for her relief before the return of another menstrual period, as it was feared she would not be able to live through another attack. The patient arrived in New York on Saturday night, pulseless at the wrist, the extremities cold, the mind lethargic. There was ovarian enlargement with tenderness. After a consultation it was decided to operate the next morning, but, when morning came, two hours were spent in stimulating the patient, to put her in a condition at all suitable for an operation. It was probable that not more than a wineglassful of blood was lost during the operation. The right ovary was removed with some difficulty. The left one was as large as a hen's egg, and bound down by adhesions. While he was endeavoring to liberate it it burst in his hand, and material escaped which felt like lumps of charcoal. It proved to be a black, granular mass, probably composed of coagulated blood which had become encysted within the tumor. This ovary also contained several cysts, and both organs were in a state of congestion. The patient rallied well just after the operation, her mind was clear, and she said she felt better than for many months, and confidently believed that she would recover. But the following morning the temperature rose to 105·5° F., and, although it was readily reduced temporarily by the coiled tube conveying water, it would again rise, and death seemed inevitable. At 4 P. M. the pulse could scarcely be felt at the wrist. By request, Dr. Howe transfused about three ounces of blood and an equal quantity of salt and water. But neither the pulse nor the respiration showed any marked improvement, and she died in the morning. Death might have been accelerated by shock, but it was thought to be chiefly due to inanition and loss of nerve power resulting from protracted illness.

Dr. DAWSON was of opinion that the blood-clot removed from the left ovary was formed at the last menstrual period, when it was feared the patient would die. He attributed her symptoms to the condition of the ovaries, and said that, had an operation been allowed when he urged it six months ago, the patient would have stood a better chance of recovery, and would have been spared months of extreme suffering.

Dr. A. JACOBI said that, in order to complete the history of the case, one or two things would be desirable. One was, recovery after the operation; another, since the patient had died, a post-mortem examination, and he would suggest that, if it was possible, one should yet be made. Those who had listened to the history had not seen the patient; certainly Dr. Dawson had, and he had given reasons why he had regarded the symptoms as of reflex origin, and therefore had operated upon the ovaries. But possibly an autopsy would give a clew to the origin of the symptoms, as it had done in some other cases, in a direction different from that to which Dr. Dawson had pointed. He would not say that this was one of the cases, but meningitis, more or less localized and more or less old, had given rise to a great many symptoms which had very frequently been mistaken for reflex symptoms. He therefore thought that a post-mortem examination would be very important in order to determine absolutely that there was nothing in the brain which might explain the symptoms. If nothing was found in the brain he would certainly be of the same opinion with Dr. Dawson, that the ovaries were the cause of all the symptoms complained of for so many years.

Dr. DAWSON remarked that the maniacal symptoms dated back only a few menstrual periods, and that after the operation the patient became clear in her mind. The history was not one of meningeal trouble.

Dr. JACOBI said there were many cases of meningitis which did not show pathognomonic symptoms. He did not think our knowledge of reflex symptoms was sufficiently advanced to enable us always to exclude disease of the central organ of which we knew so little.

Dr. DAWSON said that a year ago, at the request of Dr. C. H. Brown, he saw a woman with mania, in whom he detected an enlarged ovary, and, inasmuch as there was a possibility of the mental trouble being of reflex origin, he advised an operation, which was consented to. The specimen was shown to the society. He saw the woman about six weeks ago, and her husband told him that she was herself again, and absolutely free from maniacal symptoms; the operation, he said, had cured her. A month ago, however, her symptoms of mania had returned. This case would go to support the view taken by Dr. Jacobi that we were in ignorance of the influence which disease of the ovaries might have in the production of mania.

Dr. HUNTER thought that time enough was not always allowed to elapse after removal of the ovaries before denying its beneficial effect. He recalled a case operated upon by Dr. Thomas some years ago for the relief of maniacal symptoms for which the patient had been restrained nearly a year. Both ovaries were found to be diseased, but no improvement followed their removal; the patient became a hopeless maniac. But, after the lapse of a number of months, improvement began, and now, two years after the operation, the patient was perfectly well. She had been a burden to her household for ten years. Dr. Hunter had seen several other cases in which recovery did not begin to take place for from twelve to eighteen months after removal of the ovaries for symptoms attributed to disease of those organs.

Dr. JACOBI inquired of Dr. Hunter whether he attributed the patient's improvement eighteen months after the operation to removal of the ovaries.

Dr. HUNTER replied that that was the deduction; there was no question as to disease of the ovaries; they were both cystic. The symptoms of mania began with dysmenorrhœa, and were aggravated during each menstrual period.

Dr. JACOBI thought that such cases ought to be accepted with a good deal of doubt. Eighteen months was a long time to wait after an operation for recovery to take place; he did not think that so great a length of time should be required for

the absorption of inflammatory deposits which might have occurred in the neighborhood of the diseased organs and caused a continuance of the symptoms. Besides, there were many cases of mania which got well without removal of the ovaries, and cases of the kind related by Dr. Hunter should not, therefore, be allowed to prove too much in favor of the operation.

Dr. Hunter remarked that in the case to which he referred menstruation had continued with more or less regularity a year or two after the operation. He had records of cases in which menstruation had continued for about a year after the operation. If the periods continued to recur for a year, it was not unreasonable to suppose that improvement would begin at the end of that time. He believed, with Dr. Jacobi, that it would require a number of cases to prove the matter positively.

The Chairman inquired whether we were to understand that the improvement began with the cessation of menstruation.

Dr. Hunter replied in the affirmative. He further referred to a case of which he had very full records—that of a woman who had suffered from dysmenorrhœa of increasing severity for eight years. She preferred death to her condition before the operation. No marked improvement followed the removal of the ovaries, and at the end of six months she was still suffering from severe pain. At the close of the year, however, she wrote that she was perfectly well. She menstruated about the eleventh month after the operation. One ovary had been found to be enlarged and cystic, and both tubes were enlarged.

Prolapsus of the Rectum.—Dr. A. Jacobi related the history of a case of prolapsus of the rectum in a child nearly three years of age, which was presented at his clinic recently. As it entered the room it walked a little peculiarly, as if suffering from soreness of the inguinal glands. It was unable to have a movement from the bowels without straining, and in the passage of both fæces and urine was obliged to lie upon the belly and face. Dr. Jacobi attempted to place the boy upon a chair, but he struggled against it, and his mother said he was unable to sit. On letting his pantaloons down it was observed there was prolapsus of the rectum a distance of three inches, presenting the appearance of a sausage of a dark-red hue. The protrusion bled very easily when touched. At the outer end was an opening, into which he inserted his thermometer-case to take the measurements. As the silver case passed the anus it was grasped rather tightly, which would explain why there had been difficulty in having passages. This condition had lasted for three weeks. An attempt had been made at reduction, but unsuccessfully. Dr. Jacobi supposed the intestine, being so tightly grasped by the anus, could not be in a healthy condition, and, on examining the parts with great care, he found that at the seat of the constriction there were numerous cuts, with rough edges, of varying depth, some extending as deep as the peritoneal coat, showing that amputation of the protruded gut was gradually taking place. He certainly would not undertake reposition at the college clinic-room, and, accordingly, had the child sent to Mount Sinai Hospital, there to be kept under observation. It seemed wiser to allow the colon to become gradually amputated than to undertake reduction, in view of the liability of tearing the exposed peritonæum. He drove to the hospital himself shortly after the child was sent, to instruct the house physician to do nothing in the case except under his directions or those of the physician in charge. He was told the next day that one of the assistants, on seeing a case of prolapsus of the rectum enter the wards, availed himself of the absence of the house physician, and squeezed and handled the parts long enough to reduce the protrusion. The next day the child had some difficulty in passing fæces, but the difficulty disappeared by the third day. Little or nothing that was peculiar could be felt in the rectum; probably the incarcerated parts were too high to be reached. But the patient was unable to pass urine, and the catheter had to be used. Six or seven days afterward, learning that the elastic catheter had been used two or three times daily by the nurse in the presence of the house physician, Dr. Jacobi told the physician to employ a silver catheter so that the bladder could be properly explored. A good deal of difficulty was experienced in introducing the catheter; the bladder was bent at its neck, and some force had to be employed to overcome the obstruction. Before the catheter was withdrawn the curve was turned, which straightened the canal, and no further difficulty was experienced in urination. It was not easy to say what had caused the flexion of the neck of the bladder to become aggravated on the reduction of the prolapsed rectum. It could not very well have been caused by peritonitic adhesions, for the reason that one introduction of the silver catheter, with anteflexion of the bladder to the normal or nearly normal position, was sufficient to relieve the trouble. While the child at present seemed to be quite well, an important question arose as to what would be the final result in the case. It was hardly possible that a considerable amount of cicatrization would not take place where there had been partial amputation of the gut, and it seemed more than probable that in the course of time the child would suffer from stricture of the intestine. If this should occur, the case would be a difficult one to treat, because of the marked sigmoid flexure which existed in children. Had spontaneous amputation taken place the child would have been under his immediate observation, and it was not probable that it would have been attended by any serious danger, inasmuch as a portion of the gut was sometimes successfully amputated in intussusception.

The Chairman thought there was at present danger of fæcal matter becoming lodged in some of the cuts within the intestinal coats, and producing further injury.

B. F. Dawson, M. D.,
Frank P. Foster, M. D., *ex officio*,
Committee on Publication.

Miscellany.

The Albany Alumni Lectures.—The "Albany Medical Annals" announces that the next course will be given on the 3d of March, 1886, by Professor S. Oakley Van der Poel, M. D., LL. D., of New York, on "Hygiene; its Relations to the Profession and the General Public."

The Republic of Guatemala owes a debt of gratitude to a physician of this city, who, according to the "Eastern Medical Journal," has presented a collection of serpents to the American Museum of Natural History which consists of "all the serpents of the Republic of Guatemala." Surely an easier way of ridding a country of snakes can scarcely be imagined, although our contemporary does not give us the *modus operandi* by which it was accomplished.

Infectious Endocarditis.—We are indebted to Dr. John H. Musser and Dr. George A. Piersol, of Philadelphia, for a copy of their pamphlet entitled "Notes of a Case of Infectious, so-called Ulcerative, Endocarditis, and of a Case of Acute Pericarditis," extracted from the "Transactions of the College of Physicians of Philadelphia." It has seldom been our fortune to meet with so satisfactory a clinical study, and we would particularly commend the photographs, by Dr. Piersol, which accompanied the copy sent us. They seem to represent the perfection of the photographic art as applied to medicine.

The French Medical Year-Book.—We have received from the publishers, the Messrs. E. Plon, Nourrit et Cie., of Paris, the seventh volume of the "Année médicale," for the year 1884. This excellent pub-

lication, edited by Dr. Bourneville, the *rédacteur en chef* of the "Progrès médical," with the collaboration of a number of eminent practitioners, furnishes a *résumé* of the progress of medicine during the year. It is divided into departments corresponding to the practical branches, and an excellent index makes it easy of reference.

Parturition and Measles.—Dr. A. R. Simmons, of Ithaca, N. Y., writes as follows: "On the morning of March 22d I first saw the patient. On Friday morning, the 20th, she had complained of headache and sore throat, and the next day she had begun to cough. That night labor pains set in and continued all night. The next morning I found the mouth of the womb patulous, but the pains had nearly ceased. The conjunctivæ, the roof of the mouth, and the throat were then reddened, and she coughed a little. Labor pains began again about 6 P. M., and the child was born about 1.30 A. M. It was a normal labor in every respect, and the signs of measles were then very prominent. Seven hours afterward the measles rash was out on her face and neck, there was some delirium, the pulse was 128, and the temperature was 104° F. I was obliged to catheterize her, and continued to do so until April 3d; the expulsive power and the desire to urinate were wanting. The average daily quantity of urine was about a pint, and it contained no albumin or casts. On the 24th the pulse was 108, and the temperature 100°; the tongue was moist. She had passed a very good night, but with some delirium. The rash covered the whole body; the cough was severe, the result of the usual bronchitis; there was some soreness over the bowels, but pressure was very well borne; the lochia were normal; the bowels had moved. At night the pulse was 100, and the temperature 101·3°; there was no tympanites. On the 27th the temperature was 100·8°, and the pulse 120; there was no tenderness of the abdomen, but her back ached; the lochia were offensive, but normal in quantity; the breasts were full of milk. In the afternoon the temperature was 99°, and the pulse 100; a free movement of the bowels had been secured, which had relieved her. From this time she convalesced rapidly, and was sitting up on the sixteenth day after delivery.

"I consider that there was no possibility of error in the diagnosis of measles; a very extensive epidemic was raging at the time, and a case had occurred in the same house early in the month. Knowing that the pregnant woman had not had measles, I advised her removal from the house, but it was not done. The baby coughed some on the 29th and 30th of March, and a rash appeared on the latter day, but, when I saw it at night, it was hardly perceptible, and it was all gone the next day. The child had a convulsion on the 2d of April, but, has since been well. I will add that in the same epidemic a child seven weeks old had the measles a week after its mother was attacked. Both recovered."

Congenital Dislocation of the Patella.—A correspondent writes from Louisville, inclosing a letter from a former pupil of his, asking for information bearing upon the following case: A girl, seven years old, having loose joints, although in robust health, has the patella resting on the external condyle. It is easily replaced while the limb is extended, but requires considerable force to keep it in place during flexion. Both limbs are affected alike. The girl's father, her aunt, and the aunt's daughter, all have their patellas resting on the outer condyle. The doctor asks: Can anything be done to rectify the deformity, what can be done, and is there anything in literature in regard to such an hereditary deformity?

Prevailing Diseases in Illinois.—A correspondent writing from Stillwell, Ill., says that he has encountered an "epidemic" of inflammatory rheumatism and one of paralysis in both children and adults; also that he has regularly to contend with typho-malarial fever in the autumn and cholera infantum in the summer. He would be glad to receive hints as to the management of these various affections.

A Correction.—We regret that an error crept into our report of the proceedings of the recent annual meeting of the Illinois State Medical Society. In the issue for June 20th, page 701, we gave an abstract of a paper entitled "How the Vitality of a Seed is Preserved," and credited the paper to Dr. H. Judd, of Galesburg. The paper, we now learn, was really read by Dr. A. Wetmore, of Waterloo, and we take pleasure in making the correction.

THERAPEUTICAL NOTES.

Veratrum Viride in the Treatment of Palpitation.—M. Sée ("Union méd."; "Dtsch. Med.-Ztg.") recommends the use of tincture of veratrum viride for controlling over-action of the heart in cases of exophthalmic goître. From three to five drops are to be given three or four times a day, for several weeks or months together.

Persian Insect Powder as a Medicine.—The "Deutsche Medizinal-Zeitung" alludes to the fact that a Russian physician, Dr. Swiontezki, has lately recommended an alcoholic extract of Persian insect powder, with the addition of santonin, as a "sure cure" for cholera; and then quotes from another Russian source to the effect that enemas of the insect powder are effective in the treatment of ascarides, and have no poisonous action.

Massage in the Treatment of Fæcal Accumulation.—Kriwjäkin ("Protok. der kankasisch. med. Gesellsch."; "Dtsch. Med.-Ztg.") reports four cases of obstinate constipation, varying from eight to twelve days in duration, in which the trouble was overcome by deep massage. The fingers, previously oiled, are to be pressed firmly upon the abdomen, and movements of massage are then to be executed, especially upon those parts where hardened masses are felt. The process is to be continued for twenty minutes, and repeated at intervals of an hour and a half until the bowels are moved.

Strychnine in the Treatment of Supra-orbital Neuralgia.—Howe ("Revist. Argent. de Buenos Aires"; "Dtsch. Med.-Ztg.") has succeeded in curing with strychnine a patient who had suffered for fifteen years with a neuralgia that had resisted all other treatment. Four hypodermic injections of the drug were given at the seat of the pain, and this was followed by improvement. The subsequent injections were thrown into the back. The treatment lasted three weeks, and the result is said to have been brilliant.

Sucupira.—This seems to be the generic name of the *soukoupire*, a tall tree found in several varieties in Brazil. According to M. Campardon ("Gaz. hebdom. de méd. et de chir."), the Brazilians use the bark as a depurative and to mitigate the pain of rheumatism.

Iodine and Pyridine in the Treatment of Asthma.—The alkaloid termed pyridine (C_5H_5N) is a colorless, volatile liquid, of a very penetrating odor, miscible with water, and forming with the mineral acids salts which are very soluble but unstable. It is obtained by the dry distillation of various organic substances, such as Dippel's animal oil, certain alkaloids (including cinchonine, quinine, morphine, and atropine), and coal-tar. It is found also in the condensed products of tobacco-smoke and in nicotin itself. M. Germain Sée lately read an interesting paper before the *Académie des sciences* ("Rev. méd.") on the use of pyridine in the treatment of asthma. He declares that iodine is the greatest curative agent in this affection, whatever form it may take, and that pyridine is the best palliative for use during the attacks. It causes a decided and immediate diminution of the feeling of oppression, so that the breathing becomes calm, while the action of the heart preserves its regularity as well as its force. After about an hour there is in many cases an irresistible desire to go to sleep, but no stupor or any approach to anæsthesia, although the reflex excitability is diminished. The remedy should be given by inhalation, a fluidrachm or more being poured on to a napkin in a close room. The inhalation should be continued for twenty or thirty minutes, and should be repeated three times a day. After two or three inhalations, auscultation will show great improvement of the physical signs. A few persons seem to have their susceptibility to the action of the drug impaired at the end of a week or ten days, and then it is well to begin with the iodine treatment.

Preparations of Iodoform.—The same journal quotes from the "Courrier médical" as follows:

Iodoform	15 grains;
Glycerin	5 drachms;
Essence of mint	6 drops.

Used on vaginal tampons.

Iodoform	15 grains;
Glycerin	75 "
Distilled water	3 ounces.

For injections in cases of gonorrhœa and chronic catarrh of the bladder.

Iodoform		15 grains;
Sulphuric ether, Olive oil,	each	75 "

For subcutaneous injections in cases of syphilis, from half to three quarters of the mixture being used daily or every other day.

Iodoform	15–30 grains;
Potassium iodide	1 drachm;
Tokay wine	2½ drachms.

For internal use, in cases of convulsions, in doses of from three to fifteen drops, in a glass of wine, three times a day.

Iodoform	1½ grain;
Lycopodium	6 grains;
Extract of phellandrium seed	15 "

Divide into ten pills, from three to five of which are to be taken daily, for bronchorrhœa or emphysema. It should be borne in mind that the internal use of iodoform disposes to hæmoptysis.

Discs for Sick Headache.—At a recent meeting of the *Société de thérapeutique* ("Progr. méd.") M. Mayet, fils, stated that he had had discs made after the following formula:

Menthol, Chloral hydrate,	each	7½ grains;
Spermaceti		30 "
Cocoa butter		15 "

A disc is to be bound on over the seat of the pain. M. Mayet said that he had never observed that these discs had an irritating effect.

Erythrina Corrallodendron as a Calmative.—Bochefontaine and Rey ("Année méd.") have found this plant, which is in common use in Brazil, where it is called *mulungu* or *murungu*, of service as a calmative and hypnotic in the agitation and sleeplessness of the insane, seven or eight grains of an extract being sufficient to cause sleep in such cases.

The Treatment of an Acute Attack of Articular Gout.—In a recent monograph by Dr. Robson Roose (London: H. K. Lewis), the author says that, when called to a case of this sort, he invariably examines the urine for albumin. If he finds none, and there is constipation with signs of congestion of the liver, he orders two or three grains of calomel, to be followed by a draught containing sulphate and carbonate of magnesium. If there is no marked evidence of hepatic congestion, milder remedies will suffice for the constipation; the saline draught alone, or ten grains of pilula colocynthidis et hyoscyami, with perhaps a grain of calomel or a quarter of a grain of resin of podophyllum, generally producing a free action of the bowels. At the same time he orders a mixture containing ten minims of wine of colchicum and from ten to twenty grains of some alkaline salt, such as bicarbonate of potassium or of sodium, carbonate of magnesium, or citrate of magnesium or potassium. This should be taken four times in the twenty-four hours, and continued according to circumstances. If there is much fever, two drachms of solution of acetate of ammonium may be added to each dose. The following application gives great relief from the pain:

Extract of belladonna	2 drachms;
Glycerin	½ ounce;
Water	2 drachms.

It is applied to the affected joint on cotton wool, and the part should be raised on a pillow and kept in a comfortable position. While active symptoms continue, the diet should be restricted to such articles as arrowroot, sago, gruel, milk puddings, etc. Seltzer, Apollinaris, or any other aërated alkaline water may be used freely. When the acute symptoms have subsided, beef-tea, fish, and chicken may be taken in small quantities, but the return to the usual diet should be very gradual. Rest and care are essential for some days after the subsidence of the paroxysm. Leeches, blisters, and especially cold applications, should be avoided.

The Hygiene of the Lying-in Chamber.—In a recent address before the Medical Society of the County of Albany ("Albany Med. Annals"), Dr. T. K. Perry said: "I attend everything that I am called to within the legitimate domain of my profession, from scarlet fever to phagedenic erysipelas. I witness, assist in holding, and hold a fair number of autopsies every year, and all this time keeping right on with my obstetric work without regard. I have never ordered the paper from the walls of the expected lying-in chamber, nor have I ever had them sized with a solution of mercurie bichloride. Neither do I immerse hands or instruments in any disinfectant previous to or during attendance on these cases. I will also add that I have never in a single instance employed intra-uterine injections at such times, contenting myself with simple vaginal douches; and, notwithstanding this very great carelessness and almost criminal neglect on my part, I am still able to hold up my hands for inspection, and find them perfectly clean, washed of even the stigma of misfortune. Not a death has occurred to any patient I ever attended during confinement, save as above reported [two deaths from hæmorrhage and one from eclampsia]; and, although I have many times witnessed chill, fever, abdominal tenderness, etc., hot water *per vaginam*, hot fomentations to the abdomen, diet, and anodynes have constituted and completed the treatment and cure."

Inhalations of Oxygen for Puerperal Convulsions.—It is known, says Holstein ("Gaz. méd. de Paris") that oxygen has the property of enfeebling, or, to use a fashionable term, "inhibiting," exaggerated reflexes. On the strength of this fact, Professor Lachkiéviteh, of Kharkow, lately proposed inhalations of oxygen in cases of puerperal eclampsia of reflex origin. In two consecutive cases Favre ("Wratch"), acting on the suggestion, has produced truly brilliant results. He is convinced that a bag of oxygen will soon be considered as indispensable in lying-in hospitals and obstetrical clinics as the forceps, the craniotclast, and other like instruments.

Tannate of Mercury in the Treatment of Syphilis.—According to Leblond ("Gaz. hebdom. de méd. et de chir."), this new preparation of mercury (the *hydrargyrum tannicum oxydulatum* of the Germans) has the composition $Hg_2(C_{27}H_{19}O_{17})_2$. The simplest way of preparing it is by adding to a solution of mercurous nitrate a slight excess of sodium tannate in solution. The tannate of mercury falls in the form of a yellow precipitate which rapidly turns green. It is washed by decantation until the washings no longer precipitate on the addition of acetate of lead, and cease to show an acid reaction. The precipitate is then collected on a filter and dried in the open air. It is insoluble, and should be given in the form of pills, for which Casanow's formula is as follows:

Tannate of mercury	45 grains;
Extract and powder of licorice	q. s.

Divide into sixty pills; two to be taken twice a day, after eating. The salt is incompatible with alkalies, even in weak solution.

The Action of Veratrine in Cholera Nostras.—Schulz ("Dtsch. med. Wchnschr."; "Ctrlbl. f. klin. Med.") infers that the effect of this alkaloid in the treatment of cholera nostras is not due to its action on the micro-organisms, but to its inducing a temporary hyperæmia of the intestine, whereby the resisting power of the latter is enhanced.

Lotions for Pruritus of the Genitals.—A contributor to the "Union médicale" credits Doyon with the following prescriptions:

Bichloride of mercury, Chloride of ammonium,	each	4 grains;
Almond mixture		13 ounces.

In case this fails, use:

Chloral hydrate	75 grains;
Rose-water	3 ounces;
Distilled water	4½ "

After the parts have been bathed with the lotion, they are to be powdered with starch.

Cocaine in the Treatment of Sore Nipples.—Herrgott ("Ann. de gynéc."; "Union méd.") sums up his experience as follows: 1. All the women with sore nipples who came under observation were able to give suck without pain after a four-per-cent. solution of cocaine hydrochlorate had been applied to the nipple. 2. The condition of the nipple was improved, and, where the cracks were not deep, they disappeared rapidly. 3. Cocaine should be used whenever the nipples are sensitive, in order to prevent fissures, the latter being often due to a shrinking movement on the part of the mother whenever the child seizes the breast.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M. D., NEW YORK.

LECTURE I.

(*Continued from page 715.*)

THE CHOICE OF A BATTERY AND ELECTRICAL APPARATUS.

In selecting a battery for purely medical purposes, the chief objects to be attained are (1) *cheapness;* (2) *constancy of the elements*, and their *accessibility for repairs, cleaning*, etc.; (3) *durability of the elements;* (4) a *sufficient number of elements;* (5) *ease of renewal of the elements;* (6) *ease of introduction of any number of elements into the circuit;* and (7) an ability to select such as may be required *from any part of the battery.*

FIG. 26.—THE PHYSICIAN'S HANDY CABINET BATTERY.—The accompanying cut represents a light and compact form of cabinet battery, designed by the author. It is on castors, and can be wheeled about the consultation-room. This admits of the use of the instrument when the patient is in the gynæcological chair or upon the office lounge; or when any form of fixed apparatus, such as the laryngoscope, the inhaler or spray, etc., is being simultaneously employed. In some of my later models an immovable tray is placed beneath the battery for electrodes, and a movable shelf is also provided upon which a milliampère-meter, the solution of table salt, and the electrodes in actual use can be set. A glass cover protects the battery from dirt when not in use. *E*, faradaic coils; *K*, plunger; *G*, faradaic binding-posts; *F*, interrupter; *D*, drip-cup; *R*, current-selector of single cells; *S*, the same of four cells to each button; *M*, coil to work the interrupter for the galvanic current; *L*, switch to work or disconnect the interrupter (*V*); *P*, galvanic binding-posts; 3-5 and 4-6, connecting rods to allow of the action of *M*. The commutator lies above *P*.

For the general practitioner it is necessary, as a rule, that a galvanic or faradaic battery *shall be arranged for transportation;* hence the cups which hold the fluid should have a rubber cover, or some other device which will preclude the possibility of spilling the fluid. Again, some of the batteries manufactured are liable to become rapidly oxidized by the fumes of the battery fluid. This tends to destroy their durability, and to cause difficulty in keeping them in good working order. Finally, it is very desirable that portable batteries should be as light as possible, and not too large to be handled easily.

The *attachments upon the key-board* of every portable galvanic battery should comprise a current-selector and a commutator. There should be at least four rheophores, in order to make allowance for breakage, additional connections, etc. Several electrodes of different sizes and shapes should also be selected—preferably a large, a medium, and a small one—a wire brush, and an interrupting electrode. These can be added to as circumstances demand.

For office purposes a CABINET BATTERY has some decided advantages over a permanent one placed in an adjoining closet or cellar and connected, by means of wires, with a key-board in the consulting-room. A cabinet battery can be easily wheeled about, and is readily repaired. The cabinet should be so arranged as to allow the back and front of the compartment for the cells to be removed, in case the battery needs repairs, or a renewal of the fluid. The connections of the battery with the key-board should also be made as easy of access as possible; this decreases the expense of alterations or repairs when such become necessary. They should be protected, moreover, as far as possible, against oxidation and dirt.

The cabinet battery which I use in my own office was made, under my special direction, by Waite & Bartlett, of this city, and is as nearly perfect as one could desire. It contains *forty cells of the Leclanché pattern*, which are equivalent to sixty of the gravity cell. The connections and the cells can be exposed and easily reached by removing the front and back of the case. The accompanying cut represents its special features better than a verbal description. Considerable expense in constructing such a battery may be saved in the case, and by dispensing with some of the accessory apparatus shown.

The *gravity cell* makes a very serviceable and durable permanent battery for office work. It has one advantage over some other cells—viz., that it has great constancy of action and that its activity can be renewed by the addition of crystals of sulphate of copper to the fluid when necessary without disturbing the cells. For this reason the sulphate-of-copper cell, in some one of its various forms, is employed exclusively in telegraphic lines. It can not be transported, however, about the room to suit the convenience of the patient or the physician during his examination so well as some other cells adapted for a cabinet battery. It is also difficult in many cases to repair the wire connections of a fixed battery (running, as they often do, through partitions and plastered walls to reach the key-board) when they become inefficient from any cause.

A PERMANENT BATTERY is somewhat cheaper to construct and takes up less room in the office than a cabinet, because no

case is required; but, in my opinion, these two advantages are not sufficient to render it preferable to the other for office or experimental work. I have known several of my medical friends to discard it (after a thorough trial) for a cabinet battery. If a permanent battery is deemed preferable by any of you (for reasons of your own) rather than a cabinet battery, be sure and place your cells on shelves in your office or waiting-room, and not in a cellar. The wires will not be so liable to corrode from dampness, and the cells will be constantly under your eye, so that you can see when they require attention.

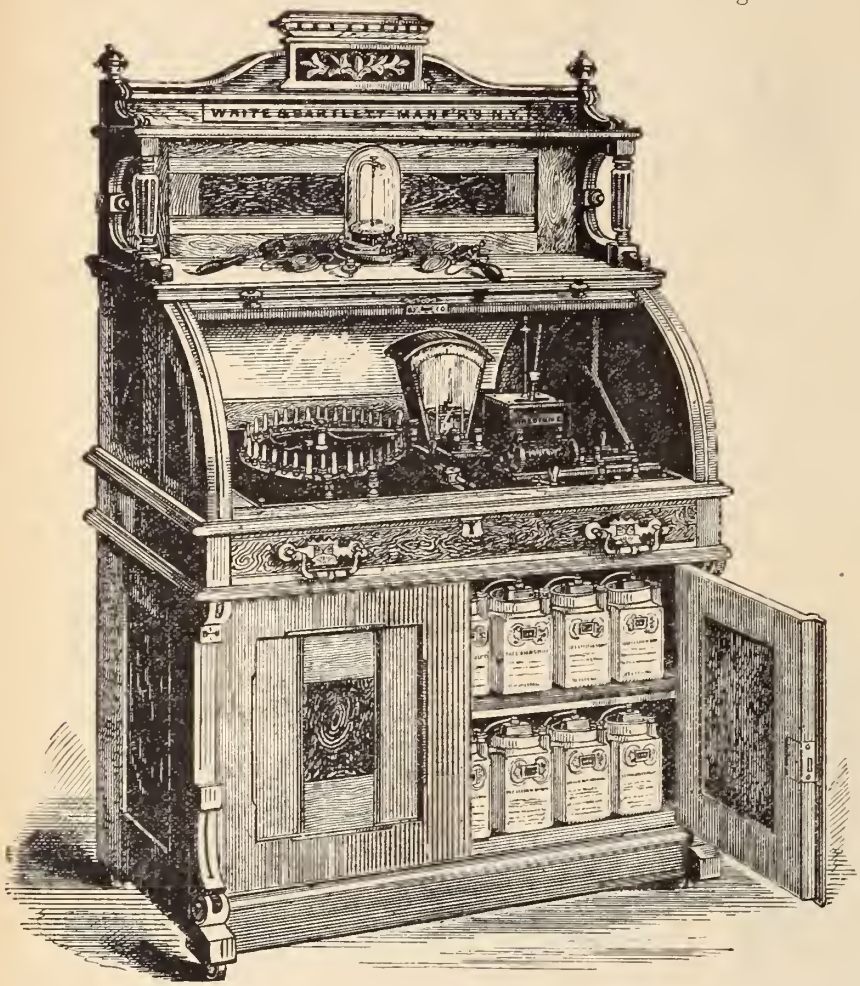

Fig. 27.—Large Cabinet Battery. From a photograph of one used by the author, and constructed from designs specially furnished by him. The current-selector and rheotome differ in several respects from those commonly used. The faradaic attachment has a Du Bois-Reymond coil. The milliampère-meter shown in the cut is that devised by Dr. Rudisch. I am at present engaged in the construction of one of a novel pattern, which I hope to present to the profession hereafter. The cells are of the Leclanché pattern. The faradaic attachment is operated by a Fuller's cell.

Respecting the selection of the cheaper forms of batteries for general medical use, it is important that accuracy of workmanship shall not have been sacrificed in order to lessen the cost. The construction of the primary and secondary coils of a faradaic machine and the adaptability of the interrupter to slow and rapid breaks in the circuit should be looked into before a decision is reached. Poor coils and a bad interrupter render a faradaic machine almost worthless. A "*drip-cup*" containing mercury, in which the zinc element is placed when the battery is not in use, is a desirable feature in a faradaic machine.

Do not buy a magneto-electric machine whose motor power is furnished by a crank to be turned by the hand. It is practically useless for medical purposes when compared with a good faradaic instrument.

The Grenet cell is now used by most of the manufacturers of electrical apparatus for a portable galvanic or faradaic battery. It is the best cell for many reasons. A thirty-cell galvanic battery gives all the current that is required by the general practitioner. Personally, I prefer the one made by Waite & Bartlett, of this city, over that of other manufacturers, on account of its modified current-selector (Fig. 23). It does not oxidize as do other forms of batteries (which have a dial current-selector attachment) when in constant use. It is also cheaper than those made by many other firms. Every galvanic battery should have a *commutator* on the key-board. Without this appliance electro-diagnosis becomes difficult.

Respecting the purchase of a STATIC ELECTRIC MACHINE, it may be well to state that a good one is quite expensive, and is only adapted for office use. I am convinced that static electricity has some points of advantage which can justly be urged in its favor as a therapeutical agent, but it can never be extensively employed or take the place of galvanic and faradaic currents. Its use unquestionably creates a profound impression upon the mind and body of the patient. He sits upon an insulated stool, sees the "wheels go round," feels himself getting charged with electricity, and is made painfully conscious of its presence when sparks of an inch in length are elicited from his surface and through his clothing. How much of the reported benefits derived only from the use of this instrument are due to the mental impression so made upon the patient is still a problem which I have not solved to my satisfaction.

The best American instrument of this kind is probably made by I. & H. Berge, of New York. It works well in all weathers, and their largest machine will produce a spark eight inches long. The electrodes for static electricity have to be made specially for its use. They must be well insulated by means of glass or hard rubber. Dr. W. J. Morton * has done much to popularize the use of static electricity in this country. A water-motor is required to run a large static machine with uniformity, although it is not absolutely essential to its use in medical practice, as hand-power will answer all practical purposes. A single-plate

* "Medical Record," April, 1881.

machine is but a toy as a means of treatment of nervous diseases. *Sufficient quantity*, as well as length of spark, is essential to the satisfactory employment of static electricity. My own machine consists of six revolving twenty-inch plates and three stationary plates. It works well in all weathers, and gives as large a quantity as any patient can bear.

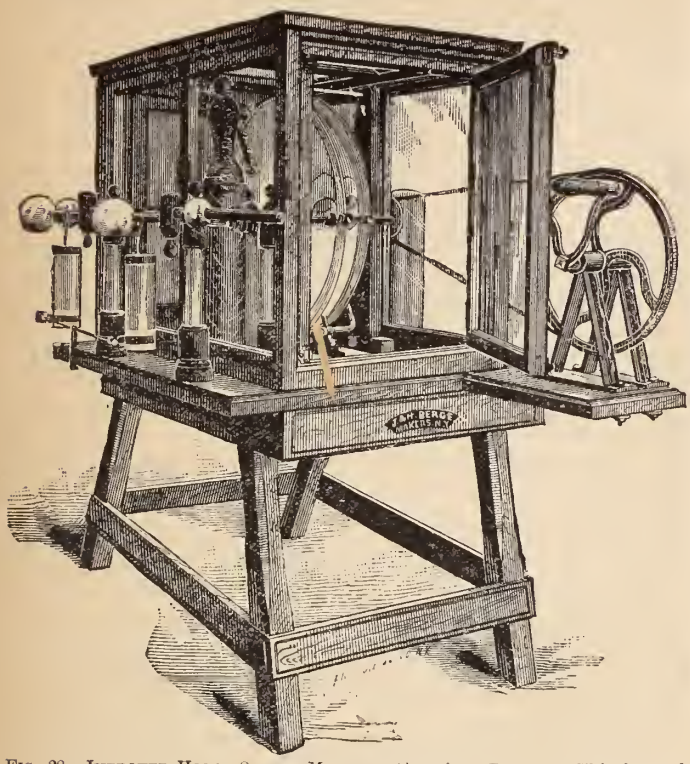

FIG. 28.—IMPROVED HOLTZ STATIC MACHINE (American Pattern). This form of machine is the best now offered to the profession. The author is at present engaged in devising some radical improvements upon the instrument which will (in his opinion) greatly enhance its practical utility and reduce its cost.

The following deductions express my convictions regarding the therapeutical value of static electricity, derived from an experience with it in quite a large number of cases:

1. In certain diseased conditions I regard its effects as more instantaneous and satisfactory than those of galvanism or faradism.

2. A machine so inclosed in glass as to prevent the action of dampness upon the revolving and stationary plates will work in all weathers, and is therefore free from the most serious objection which can be raised against franklinism. In the summer months the dampness of the air is liable to cause diffusion of the electricity generated by friction, and thus to render its employment upon a patient difficult and often unsatisfactory.

3. Quantity, as well as intensity, is requisite; hence large plates, and several of them, are preferable to any of the single-plate machines.

4. In the treatment of muscular pains, chronic muscular rheumatism, spasmodic affections, the functional nervous diseases, and neuralgia, I have found this form of electricity of great value.

5. In treating muscular pains and muscular rheumatism, spasm, and neuralgias, I prefer the spark to insulation. Patients who may have suffered for years are frequently cured in a few sittings.

6. I prefer insulation over all other methods when the tonic action of static electricity is desired. Cerebral hyperæmia and anæmia, headache, and vertigo are often rapidly relieved by this method. I frequently combine insulation with the "electric wind" (drawn from the head by means of an umbrella electrode) in these cases, as the accumulated electricity is thus concentrated toward the head.

7. Sparks are particularly to service in treating numbness and cutaneous anæsthesia. I have remarked this effect especially in the sensory disturbances which frequently accompany hemiplegia of cerebral origin.

8. Hemiplegia and paraplegia are best treated by means of the direct spark rather than the indirect spark. Sometimes quite severe shocks are required before the remedial effects become apparent.

9. Wooden electrodes are preferable to those composed of metal when employed about the eye or ear, or when the patient is very sensitive to electric currents.

10. By drawing sparks from the region of weak or diseased viscera, I have sometimes noticed very apparent benefits. Pulmonary, gastric, and hepatic disorders are often directly affected by this agent when so applied. I have relieved bronchitis in this way, and have had in some instances equally beneficial results in thus treating nervous dyspepsia, gastralgia, torpidity of the liver, etc. Some authors have reported beneficial effects from this agent in the treatment of phthisis.

11. Muscular contractions can be excited by static electricity with far less pain than by faradism or galvanism.

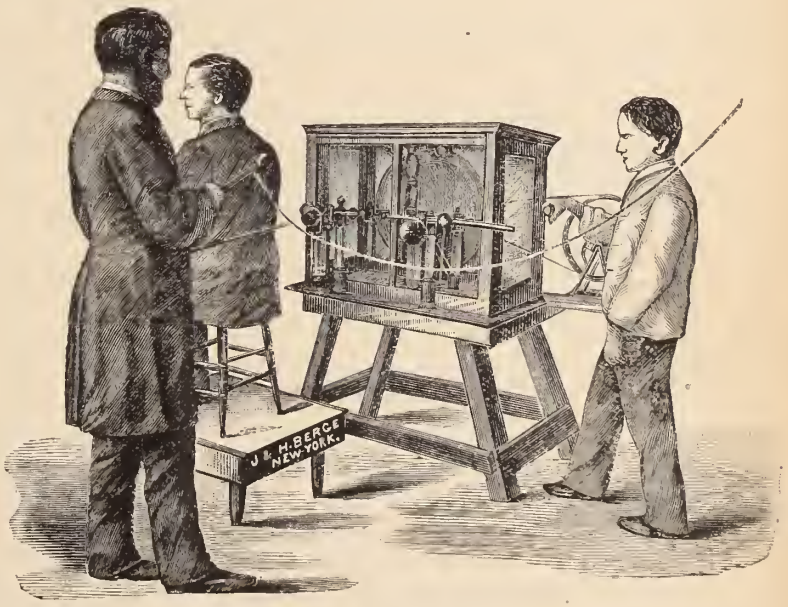

FIG. 29.—DRAWING THE INDIRECT SPARK FROM THE BODY OF A PATIENT. The chain attached to the electrode is connected with a neighboring gas-pipe or water-faucet. This cut should be compared with Fig. 3.

The so-called "static induced current" * is a very efficient way of subjecting individual muscles to the current when

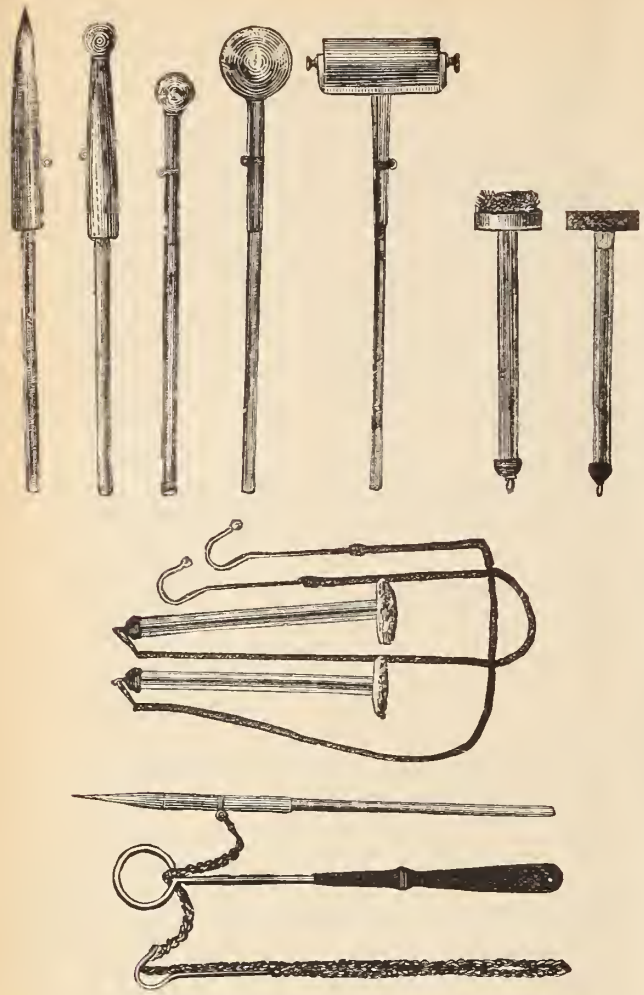

Fig. 30.—Various Forms of Electrodes Employed with a Static Machine. The handles are usually of glass. The author has substituted handles of hard rubber, which do not break easily and are equally efficient for the purpose of insulation.

their contraction is desired. The painlessness of this method is a point which alone should strongly recommend it.

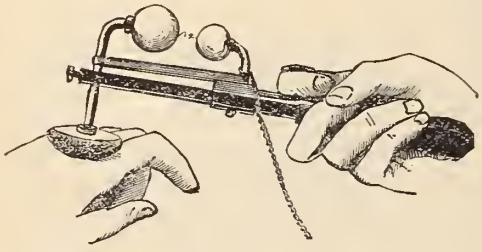

Fig. 31.—Morton's Spark Electrode. The sponge-covered tips may be of any size or shape.

12. Perhaps the most phenomenal results which have been obtained by static electricity are achieved in the treatment of hysterical patients. Hysterical aphonia, hemianæsthesia, paralysis, and hystero-epilepsy have been cured by a few sittings, by means of insulation and sparks.

(*To be continued.*)

* First described by Dr. W. J. Morton.

Original Communications.

CHOLERA ASIATICA AND CHOLERA NOSTRAS;

THEIR DIAGNOSIS AND TREATMENT,

WITH SPECIAL REFERENCE TO THE BACILLUS.*

By ARNOLD STUB, M. D.,
BROOKLYN.

Mr. President and Members of the Kings County Medical Society: At a meeting of the Royal Medical and Chirurgical Society of London, March 31, 1885, Sir Gnyer Hunter made the remark that he had not been able to find a difference between cholera asiatica and cholera nostras. Upon reading this remark, I remembered a case which occurred in my own practice, and whose history tends to support the opinion of the English physician. Permit me to relate the case:

Monday, July 26, 1881, a prominent gentleman, closely connected with one of the transatlantic steamship companies, was taken with a light diarrhœa, which continued Tuesday and Wednesday; a few dark-colored, painless stools and a feeling of being tired were not sufficient to make him call for medical aid, and he contented himself with taking a few drops of essence of ginger and some of the so-called Sun cholera mixture, which, however, did not relieve the disorder. After midnight, during the night from the 28th to the 29th, his diarrhœa increased, vomiting commenced, spasmodic contractions of the muscles of the calves of his legs and severe griping pains created considerable suffering, and I was sent for.

I found the gentleman very much prostrated. Constant vomiting of a greenish fluid, profuse odorless alvine discharges of rice-water appearance, a cold skin, an anxious countenance, cold tongue, constant spasms of the muscles of the lower extremities, and extreme prostration marked the case. I ordered at once sinapisms to various parts of the body, alternately applied, and brushing of the skin with diluted alcohol. Internally I prescribed a mixture consisting of

℞ Ol. cajeputi,
Ol. cinnamomi,
Ol. menth. pip., ... āā gtt. xii;
Sp. vini gallici ..... ℥ j;
Mist. potass. citrat ..... usque ad. ℥ vj.

M. S. One tablespoonful every half-hour until vomiting ceases.

I also ordered

℞ Mass. hydrarg. ..... gr. xx;
Pulv. opii ..... gr. viij.

M. ft. massa in pil. No. 8 divid. S. One pill every two hours.

Ice in small pieces to relieve thirst, hot flat-irons to the soles of the feet, and heated flannels to the abdomen, in numberless other cases, had not failed to give the desired relief, and when I called again, a few hours afterward, I expected to find a change for the better. However, I was sadly disappointed, and the patient remained in the same condition until next day.

On the morning of the 30th I found all the symptoms increased—the vomiting and purging were almost constant, the skin was cold and clammy, and the hands had the characteristic appearance of those of a washerwoman. If I lifted a fold of

* Read before the Medical Society of the County of Kings, May 19, 1885.

the skin from any part of the body, it remained standing in the same position for some time. The eyes were sunken, and the nose looked pinched. The whole face had an anxious and dusky look, the tongue was as if paralyzed, the voice was almost inaudible, the lips were blue, and the radial pulse could not be felt. The vomited matter as well as the rice-water discharges was strongly alkaline, and changed litmus-paper from red to blue. The urine was suppressed. I ordered at once a hot bath, and continued treatment; also ordered bags filled with hot bran to the lumbar region. To allay the excessive thirst, I ordered the ice to be continued. I also prescribed iced champagne and brandy.

August 1st, the patient became still lower. The tongue and skin were of a reptile-like coldness. A few drops of urine, drawn with a catheter, coagulated immediately upon being heated in a test-tube. Ordered one ounce of Tokay wine hourly *per rectum*, because champagne or brandy was not retained by the stomach. Directed another hot bath to be given, and called Dr. Hesse, formerly of this city, in consultation.

We both came to the conclusion to try musk and camphor, āā gr. ij, every two hours; ordered oatmeal gruel and Tokay wine *per rectum* every two hours; repeated the bath in a few hours; and continued the friction of the skin. Hot bran bags were constantly applied to the lumbar region.

The first of the powders the patient vomited at once; the second, given immediately afterward, he retained. Sometimes his stomach rejected the champagne, when we alternated the latter with iced brandy.

The following day we added strong black coffee to the stimulants prescribed, and continued this treatment until the eighth day of his illness, when his skin gradually became of natural warmth, his pulse noticeably of greater volume, his stomach less irritable, his mind less confused, and his speech more audible.

During this time he had taken every twenty-four hours one bottle of Tokay wine, with oatmeal gruel, *per rectum;* one bottle of champagne and a considerable quantity of brandy by the mouth. The urine was entirely suppressed for three days, when it returned, and became gradually less albuminous.

After the eighth day we commenced to feed with clam-broth, beef-tea, etc., and continued champagne and brandy according to circumstances. Prostration still remained.

About the ninth day well-marked typhoid symptoms developed, with a range of temperature of 102° in the morning and 104° in the evening.

At the end of the second week he complained of an intolerable itching, particularly in the face, and, in spite of all efforts to prevent him, he would scratch until the blood trickled down his face. I may remark here that no opiates had been given him for over a week. During the whole time he had been kept in a horizontal position, and even a change of garments was effected in that position. The itching lasted for about twenty-four hours, when all at once a furunculosis commenced, particularly attacking the face. Some of the boils were very tardy in healing, and had an almost gangrenous appearance in the center. The whole illness lasted five weeks, when I considered the gentleman sufficiently strong to be removed to the Catskills.

Dr. Hesse, as well as myself, came to the conclusion that this was a case identical with Asiatic cholera, although we did not feel ourselves justified in calling it by that name, because no other case of such a nature had appeared in the city. We were at a loss to find symptoms for a differential diagnosis between cholera nostras and cholera asiatica, except from the circumstance that no epidemic cholera existed in this country or in Europe.

I may add that from the time I made my first call I ordered disinfectants in the form of chloride of lime and carbolic acid to be used in the sick-room as well as all over the house, and restricted the attendance upon the patient to as few persons as possible, who avoided intercourse with the rest of the family.

During the year 1868 or 1869 I was called upon to see a case of sporadic cholera in consultation with the late Dr. Barthelness. The patient lived in Boerum Place. When I saw him the disease was in the algid stage, and all I am able to remember about it is, that he died the same day, which was the third day of his illness.

During the summer of 1866 I had spent a whole night at a boarding-house in Flatbush, whose inmates had been taken down with cholera asiatica. Myself and the husband of one of the victims were the only persons who left the house alive next morning.

I was called upon to attend the wife of this gentleman, and found a whole house full of dead and dying without a single attendant. If Dr. Conklin, who was health officer at that time, happens to be present, he will perhaps be able to refresh my memory by telling us how many people died in that house that night.

Gentlemen, I have a very vivid recollection of that terrible night and of those cases, and I assure you that I am not able to draw a line of distinction between the cases seen in 1866 at Flatbush, in the boarding-house kept by the keeper of the Penitentiary, from whence the disease had been communicated to the inmates of the boarding-house, and those cases of sporadic cholera which I have seen since, in 1868 or 1869, and in 1881.

The question naturally presents itself to my mind, Are the views of Sir Guyer Hunter correct, and is there actually no line of distinction between cholera nostras and cholera asiatica, when the first case or cases of the latter appear in a community like ours? I must answer this question in the negative as long as we take the complex of symptoms into consideration only.

But, gentlemen, within the last year or two investigations have been made into the ætiology of Asiatic cholera which bring us a step farther toward distinguishing between the two diseases above mentioned.

When I first became acquainted with the labors of Dr. Koch, and read of his discovery of the comma bacillus, I was enthusiastic in the belief that at last we had found the real cause of Asiatic cholera, and, by a simple microscopical investigation, would be able to diagnosticate cholera asiatica from cholera nostras.

But, gentlemen, here I was doomed to be disappointed. Then, immediately afterward, Dr. Prior and Dr. Finkler published the result of their investigations, and proved, or at least attempted to prove, that the comma bacillus might also be found in cholera nostras.

Dr. Deneke found the curved bacillus in old cheese, Dr. Lewis found it in sputa, and last, but by no means least, Emmerich declared that the comma bacillus was not the cause of cholera, but that a bacterium, discovered by him in Naples, alone was the whole source of the disorder.

After I became acquainted with the foregoing state-

ments I immediately began to investigate, and spoiled about a large boxful of covering glasses in the attempt to find the comma bacillus in sputa, in old cheese, in the discharges of cholera nostras, in chicken cholera, and in the discharges of typhoid-fever patients.

I certainly did find curved bacilli in every one of the specimens, but I did not find the characteristic spirillum which I found in the preparations sent me by Dr. Nicati, of Marseilles, and those I received afterward through Mr. Emmerich and Mr. McAllister, of New York, procured from microscopical laboratories in Berlin and Brussels, and representing comma bacilli artificially cultivated.

Although the curved bacilli found in cholera nostras and in old cheese are also spirilla, they are of a different size and have less of the corkscrew shape than the comma bacilli. After the former have been prepared for the cover glass and put up in balsam for examination, they assume partly the form of the cholera bacillus; but even in this condition they are larger than the latter. But if a suspended drop from the rice-water stools of a cholera-nostras patient and one from the stools of a patient suffering from Asiatic cholera are examined alongside of each other, a difference in the size and shape of the spirilla will become easily apparent. The spirillum of Asiatic cholera is only to be mistaken for that of recurrent fever, and Koch himself declares that he could not distinguish one species from the other if placed alongside of each other.

Gentlemen, I believe that Koch is correct in reference to his views of the ætiology of cholera and in regard to the bacillus question. And the reason why I think so I shall state later on.

Starting from this base, let me suppose that the cholera raging in Spain at the present time assumes wider proportions; it spreads again to France; it reaches Germany and invades England. Steamers bring us within ten or twelve days in direct communication with ports which may be visited by cholera patients at any time. One of the latter may get on board of the steamer; he may be well at the time he enters the steamer; he may be taken with a diarrhœa during the time he is on board. According to authors, the time of incubation may vary from one to fourteen days, and, if this is correct, a man may travel from Marseilles to Liverpool or London, and from London to New York, without having the slightest symptoms of cholera before he lands here, or he may have diarrhœa which may pass unnoticed by him and others; but this man, although he may never himself develop the second stage of cholera, may deposit upon the steamer, or perhaps afterward in this city, the germ which will, in a few days, infect the whole city with the pestilence, and we may never find out where it came from.

Now, gentlemen, let me suppose that such conditions prevail this coming summer; we have learned that the cholera is in France, perhaps in Germany, but not in England. The English steamers, consequently, are not subjected to quarantine. All rags have been carefully excluded from landing upon these shores, although I never heard that rags had carried the disease, provided they were not wet. And I am called, perhaps after midnight—which, by the way, seems to be the time such cases first become most troublesome—to see a patient who suffers from symptoms of cholera. The question naturally arises, Have I to deal with a case of cholera morbus or cholera asiatica? The question is an important one. Shall I notify the Board of Health, and perhaps unnecessarily alarm the community? Shall I isolate the patient, or shall I let matters go on, wait for developments, and jeopardize the lives of other people? In order to come to a proper diagnosis of the case, I proceed at once to look for the cholera bacillus in the rice-water discharges. In three different ways this object may be attained. I take two covering glasses, clean them well, after the most approved method, in nitric acid, wash them in alcohol and in ether, and afterward in distilled water.

As soon as they are dry I place a drop of the rice-water discharges upon one of those glasses with a spatula, previously sterilized by heating it over an alcohol-flame or a Bunsen burner, and spread the drop of the rice-water discharge carefully out upon the covering glass. I place the second glass upon the first and draw them asunder, in order to cause an even and uniform spread of the material upon both glasses.

As soon as they are completely dried, which will be in a few minutes, I draw them slowly three times through the flame of an alcohol-lamp, holding them with a pair of forceps covered side upward. Then I take them home and heat in a test-tube a small portion of a watery solution of gentian violet or fuchsin. As soon as the fluid begins to smoke, I pour some of it into a watch-glass, and, taking the covering glasses between two fingers, I let them drop upon the fluid with the side containing the suspected material downward. I let them swim for about ten minutes, take them from the fluid, wash them in sixty-per-cent. alcohol for about two minutes, remove the water by dipping them for a few seconds into absolute alcohol, wait a few minutes longer until they are dry, and then examine them under the microscope with a power of $\frac{1}{15}$ water immersion, or, better still, with $\frac{1}{12}$ oil immersion, and expect, of course, to be able to diagnosticate, from what I see, true Asiatic cholera or cholera morbus.

But, gentlemen, although the method above described is exactly the one used by Koch to bring the comma bacilli into view, if the material is taken directly from the patient, or if taken from an artificial cultivation, I may be sadly disappointed in all probability, because, in the first place, I may find no characteristic spirilla, and those bacilli we do find may belong, as far as their microscopical appearances show, just as well to cholera morbus; or I may find only straight, rod-like bacteria mixed with a few curved ones, such as can be seen in all the excrements of ordinary diarrhœa; because it is a well-established fact, I think, that in the beginning of Asiatic cholera the characteristic spirillum can not be immediately recognized under the microscope. A better method, however, would be to place a drop of rice-water discharge upon a covering glass, and put the latter, with the drop of fluid downward, upon a shallow glass cell; if this suspended drop, which may be stained with one of the basic aniline colors, is examined with a powerful immersion lens, it is possible that we may find sufficient evidence

to base a diagnosis upon. We shall see at least a large quantity of bacteria alive, and, if the fluid contains a sufficient quantity of the cholera bacilli, they will appear like a swarm of mosquitoes moving hither and thither, and among those there will be noticed occasionally a few spirilla of a wave-like form. So, at least, does Koch describe the microscopical appearance of a suspended drop of artificial beef-tea cultivation, and there is no doubt that the same may be observed if rice-water discharges are used for examination from a patient who has been sick for some time, but it is very doubtful if we shall be able to gain this result in the earliest stage of cholera.

Another method of distinguishing the cholera bacilli is published in the "Deutsche medicinische Wochenschrift," Berlin, April 2, 1885. Professor Max Schottelius, of Freiburg, went to Italy to study the cholera, and, being admitted into a cholera hospital of Turin, he made numerous investigations. The principal result he obtained is the following: He mixed 100 to 200 c. cm. of the suspected fæcal matter, or rather rice-water discharge, with 250 to 500 c. cm. of slightly alkaline meat-broth. This mixture must be shaken and put into a high beaker-glass. The glass must be put in a warm place, the temperature of which does not exceed 40° C., or 104° F. The fluid remains standing for from ten to twelve hours. After this time the surface of the fluid is touched with a glass rod, and a drop placed upon a covering glass; further preparation, and staining with a concentrated watery solution of fuchsin, as described before, will, under the microscope with a power of about 600 diameters, show almost a pure cultivation of the comma bacillus, if the case has been genuine cholera. Examination of a suspended drop of this mixture gives also a characteristic and perhaps still better demonstration. The surest method, however, suitable for diagnostic purposes, will be the cultivation with nutritive gelatin upon glass plates, and we shall find it of sufficient simplicity to make practical use of it, provided we are able to obtain at short notice the necessary nutritive gelatin of slight alkaline reaction. I herewith will mention briefly two formulæ found to be most efficient for use: First, 17 ounces of good, finely chopped meat, added to 34 fluidounces of distilled water, and well stirred, remains standing in the ice-box for twenty-four hours. Afterward the whole is strained through gauze by means of a press, and sufficient distilled water added to make again 34 ounces. To this must be added 2½ drachms of table-salt, and from 1½ ounce to 3 ounces of the purest gelatin; allow the whole to dissolve by gentle heat, neutralize with carbonate of sodium, and add a little of the latter in excess to give the mass a weak alkaline reaction, sufficient to turn red litmus-paper slightly blue. The neutralized solution must be boiled for an hour upon a water-bath and, still hot, filtered through paper. The filtrate, boiled again and afterward put upon ice, must be clear and transparent. During the boiling process a turbidity, caused by phosphates, may appear, which, however, will disappear as soon as the gelatin has been cooled upon ice.

Another process, described by Dr. F. Hueppe, professor of hygiene and bacteriology at the laboratory of Fresenius, of Wiesbaden, is the following: Peptone, 3 p. c.; grape-sugar, 0·5 p. c.; extract of meat, 0·5 p. c. and from 5 to 10 p. c. gelatin. I will not try your patience by giving the whole process necessary for this preparation. It will be sufficient, I think, if I mention that a little apparatus is required and a great deal of exactness and time. We, as practical physicians, may have the former, but hardly the latter, at our command, consequently I would like to take the liberty of suggesting that Dr. Squibb, for instance, take the matter in hand and prepare for us the gelatin, or that the Board of Health establish a laboratory where not only shall the gelatin be prepared, but, under the supervision of a competent medical man, such investigations carried out as I have already suggested or shall hereafter describe.

Supposing we are in possession of the necessary gelatin and desire to make the cultivation as above mentioned. For this purpose we take an object-glass, according to the size of the stage of our microscope, to enable us to examine the same afterward in all directions with a lens. We put some of the nutritive gelatin into a test-tube and warm it in hot water until the gelatin becomes fluid; then, by means of a pipette, we carefully transfer some of the gelatin to the object-glass.

The portion of gelatin transferred must be a few millimetres thick and no part touch the edge of the object-glass. Then we take, with a sterilized platinum-wire, a drop from the rice-water discharges, and inoculate the gelatin by making a few strokes upon it of not sufficient depth to reach the glass below the gelatin.

The longer our object-glass, the more strokes we shall be able to make, and the easier it will be to recognize and differentiate the colonies of bacteria which will grow there. After the gelatin has been inoculated, the plate of glass must be placed under a bell-glass whose walls are dampened inside with distilled water. This, however, is not absolutely necessary. Eighteen hours afterward we shall observe the result of the inoculation by the growth of the different species of bacilli. In case of Asiatic cholera we shall observe in the early stages of the growth a small, pale drop, not of a perfectly circular appearance, such as almost all other colonies of bacteria present, but with irregular, rough edges. From the very beginning of its growth it has a granulated appearance. A few hours after the first appearance of these drops upon the gelatin the granulation appears more marked, and looks like a mass of irregular-shaped, highly refractive granules, which Koch compares to a little pile of small pieces of glass. Within twenty-four hours the gelatin becomes fluid in the immediate neighborhood of the colony, and the latter sinks deeper into the gelatin. A small funnel-shaped impression is formed, in the midst of which the colony may be seen as a small whitish spot or dot. For the purpose of making these observations, the glass plate must be placed under a microscope and examined with a power of about eighty diameters. In order to make these cultivations, a temperature not lower than 68° F. is necessary, which during the summer months will be easy to reach. In case we have to deal with a cultivation of the bacilli of cholera nostras discovered by Finkler and Prior, we shall find discs of a regular, even shape, and within thirty hours a funnel of 1 cm. in diameter will have formed, which

in two or three days will have widened out to such an extent that the whole of the gelatin will have flowed off from the object-glass.

(*To be concluded.*)

A CASE OF COMMINUTED AND DEPRESSED FRACTURE OF THE SKULL; TREPHINING; FUNGUS DURÆ MATRIS; RECOVERY.*

By W. C. BURKE, Jr., M. D.,
SOUTH NORWALK, CONN.

C. R., aged eleven, was struck by a locomotive attached to an express-train, running at a high rate of speed, on the afternoon of November 6, 1883.

He sustained a compound comminuted and depressed fracture of the left temporal bone, involving slightly the frontal and parietal bones of the same side. The blow was given while the boy was in the act of jumping from a car directly in front of the approaching train, which he did not see. He was thrown a considerable distance to the side of the track, and, when picked up, was unconscious, breathing stertorously, and bleeding profusely from the divided temporal artery. He was taken to the accident-room at the station, and seen by me within ten minutes after the accident. At this time the pulse was very feeble and slow; breathing stertorous; pupils moderately but unequally dilated, the right more than the left. The wound was cleansed, the bleeding vessels were secured, a temporary dressing was put on, and he was conveyed to his home a mile distant. He had lost a good deal of blood.

An hour later, with the assistance of Dr. J. G. Gregory, I removed the dressings, and, enlarging the opening in the scalp, found that the skull had been fractured and depressed over an area two inches by two and a half, located a little above and in front of the left ear. The fractures did not extend beyond this oval in any direction. I found nearly all the pieces of bone lying loose in the wound, and they were easily removed. After removing all the fragments in sight and carefully cleansing the exposed membranes, I found a gaping wound of the membranes and brain substance. Gently insinuating my little finger into this opening, at the depth of an inch and a half from the surface of the skull, I felt two pieces of bone, which I cautiously removed, carrying the slender forceps along my finger as a guide. They proved to be fragments of the internal table of the skull turned edgewise and in their long diameter, evidently shot into the brain by the blow, like flying glass. These increased the depth of the wound by nearly an inch, making the wound of the brain about two inches and a half deep. The direction was obliquely downward and backward toward the pons Varolii. Considerable hæmorrhage from the brain substance was controlled after some delay. Two vessels in the external wound required ligatures.

Just as I was withdrawing the last fragment from the wound the patient gave the first symptom of returning consciousness. He groaned and turned his head partially to the left. After careful cleansing of the membranes they were smoothed out, everything being left in as natural a condition as possible, and the external wound was closed by fourteen interrupted sutures.

A compress, wet in a five-per-cent. solution of carbolic acid and secured by a roller bandage, completed the dressing. These dressings were to be moistened repeatedly during the night with the solution. He rallied well from the shock, but passed a restless night, tossing about a good deal. Sixty-nine hours after the accident he uttered his first coherent sentence, although he had spoken detached words twenty-four hours previous. Everything progressed favorably, the wound apparently healing well. On the sixth day I removed a part of the stitches, and the remainder on the seventh. When union had taken place throughout, except at the point of exit of the two ligatures, a piece of rubber tissue was laid next the wound, and over this several layers of gauze secured by the roller. The next day the dressings were not disturbed. On the ninth the boy complained of a pain in the wound, and the dressings bulged at the seat of injury. On removal, a cauliflower-like growth, protruding three eighths of an inch above surrounding scalp, had reopened the wound to the extent of the opening in the skull-bone. The edges were everted so that its diameter was a little over three inches. In the afternoon of the same day I attempted to remove a portion with the galvano-cautery, but with only partial success. Several things were tried in the next day or two, but were of no avail.

The growth by this time had increased to formidable proportions. I then determined to try the dried sulphate of zinc upon it. So I put on a free coating of this, and over it a compress and bandage, drawn as tight as the patient would allow, which was not nearly so firm as I should have preferred, as he complained that it gave him "a feeling in his head of bursting."

This dressing was allowed to remain forty-eight hours, when, on removal, I was pleased to find a slough, three eighths of an inch thick, easily removed. Another coating of the zinc was put on and similarly dressed, remaining forty-eight hours. This process was continued until all the diseased tissue had been removed down to the level of the healthy brain substance, when the zinc was discontinued and iodoform substituted. When the dressings were again removed, healthy granulations had sprung up all over the wound, and the process of repair went on as rapidly as could be desired. The constitutional treatment had been with iron and quinine—in short, supportive.

At no time had the temperature been above 101° F., and that only once, during the first forty-eight hours. A slight amount of brain substance had been lost. He was discharged, January 25th, two months and nineteen days after the accident.

A recovery from so frightful an accident is rare when we consider the extent of injury to the brain substance, the wound extending well toward a region of the cerebrum usually considered vital. And the recovery from fungus duræ matris was hardly less remarkable. There were, I believe, fifty-one cases of this disease following wounds of the brain during the late war, in which forty-five of the patients died, only 1·13 per cent. recovering. The boy is in perfect health now, and has no headache or other unpleasant symptoms. Mentally, no special change is noticeable; but his teacher thinks he does not commit to memory with quite so great facility as before the accident. But even this is doubtful.

ON THE ERADICATION OF SYPHILIS DURING THE FIRST STAGE BY SURGICAL MEANS.*

By A. H. P. LEUF, M. D., Brooklyn,
PATHOLOGIST TO ST. MARY'S GENERAL HOSPITAL, TO ST. MARY'S FEMALE HOSPITAL, AND TO THE HOSPITAL FOR NERVOUS AND MENTAL DISEASE, ETC.

Inasmuch as it was originally planned that this paper should not appear till the end of this year or the beginning

* Read before the Medical Society of the County of Kings, May 19, 1885.

of the next, I am enabled to give but an outline of what it is my intention ultimately to say upon this subject. Being but the outline of an argument in favor of a specific therapeutic measure, it will necessarily be very brief. For the purpose of economizing time, I will purposely avoid reference to authors and the discussion of the various views held upon this interesting and intricate question. Various, however, as are these views, and great as may be the intricacy of this subject, it is yet possible to reduce them to simpler proportions for convenience of analytical study and synthetical deduction. My plan, therefore, this evening, will be to submit to you only that way of viewing this question which accords with my argument, and the digressions therefrom shall be as limited as possible for the purpose of saving time.

Syphilis is a constitutional disease and contagious in the true sense of the word; that is, communicable only by contact, and therefore produced invariably by inoculation—except it occasionally be autogenetic. It is preceded by a period of incubation, and manifests itself in three periods—primary, secondary, tertiary.

The primary stage consists in the formation, growth, and decadence of a highly characteristic sore at the seat of inoculation after an average incubation of much longer duration than precedes any other sore with which it might be confounded. A variable time after the formation of this sore, or chancre, the nearest set of lymphatic glands become enlarged.

The secondary stage is ushered in by acute characteristic general signs and symptoms after a definite interval, measured by weeks, succeeding the appearance of the chancre. This continues for a variable time, to be followed by a period of quiescence, usually measured by months.

The tertiary stage exhibits itself in the form of special pathological changes in one or a number of places, and either in one or a number of tissues, at the same time or at different times. These manifestations are mostly dependent upon their location for their greatest significance. Thus, a nodular enlargement of the tibia is in itself harmless; long radii of the calvaria perhaps the same, but for the proximity of a vital organ; an exostosis within the lower part of the spinal canal, although similar in character, is not now so harmless, but, if sufficiently large, will induce paralysis of the parts below; the same projecting from the walls surrounding the medulla has a significance that is fatal; even in this latter instance the effect may be nil so long as the growth does not continue beyond a certain size. This is the general character of tertiary manifestations. A carcinoma of the breast will kill by its virulence and not by its increase in size, while the converse is essentially true of syphilitic formations.

Thus we understand that the existence of syphilis is a constant menace to the body it inhabits. Of the nature of its active principle nothing definite is known. One fact is quite universally admitted, and that is, that, when inoculation has once taken place and the chancre is formed, secondary symptoms demonstrating systemic infection are inevitable, and so, as a rule, are tertiary manifestations in the majority of cases.

As rational therapeutics preponderates over empiricism, it becomes more evident that ætiological data increase in value for the treatment of disease. A thorough comprehension of these is impossible without an exact knowledge of the minute pathological changes that accompany disordered states of the body. In syphilis we have no knowledge of the character of the virus itself. Its manifestations are known to us both macroscopically and microscopically, the latter especially in the tertiary forms. The changes it induces at the beginning, in the formation of the primary lesion, are not so well understood nor so generally accepted.

To adopt a rational plan for the interception of this poison previous to its general invasion of the body, the following questions must be answered:

1. Does the disease arise *de novo*—is it autogenetic?
2. What are the necessary conditions for inoculation?
3. What is the effect of the virus at the seat of inoculation?
4. Is there a decided interval between local and systemic manifestations?
5. By what channels does the disease enter the system—by the blood or by the lymphatics?
6. Can the progress of the virus be traced from the time and place of its entrance into the tissues until general infection has occurred?

That all this can be done I shall now proceed to demonstrate:

1. *Does the disease arise de novo—is it autogenetic?*

Syphilis must have originated at some period, and at not so remote a day but that the circumstances existing at that time to favor its production must also exist at the present day. Therefore I can not deny the possibility of its occasional spontaneous origin, although compelled to admit that it must be a comparatively rare occurrence.

2. *What are the necessary conditions for inoculation?*

These consist in the presence of the virus and stable living cells in direct contact. The cutis being composed of dead, and to some extent desiccated, cells, it is evident that inoculation can not take place through it. Observation demonstrates that this is true, for the rule is, in carefully studied cases, that a denudation of the cutis vera is a constant and necessary precursor of the chancre. I will relate an incident in point:

Two medical students, at a Western university, spent a night together in the same bed with a woman of obtuse morals. Neither student had had any sexual congress for several months preceding this night, nor did they during a long period subsequent. One developed a chancre, and, later, secondary symptoms; the other never suffered the least local or general disturbance. Circumstances would not warrant the supposition that the chancre developed *de novo*. On the other hand, it would be contrary to clinical observation and the result of scientific experimentation to suppose that the more fortunate student escaped because he enjoyed a special immunity, for he had never had syphilis. The correct solution of the problem lies in the assumption that the one affected had abraded a portion of the mucous membrane of his penis while the other had not, and this

was actually the case. This is not a lone instance; there are many others.

The denudation of the cutis vera—an abrasion, in other words—is, therefore, necessary for the introduction of syphilis through the skin or mucous membrane; that is, direct contact between the virus and the stable living cells.

3. *What is the effect of the virus at the seat of inoculation?*

It gradually, but inevitably, induces circumscribed tissue changes of a special character, which become evident only after a lapse of time varying from a little more than a week to more than two months. The tissue changes consist mainly of a proliferation of the vessel-walls and immediate fixed cells, without the usual amount of serous effusion and hyperæmia. They manifest themselves in the form of an elevated ulceroid, with a hard base, and having a serous rather than a purulent discharge. The variation in the time at which the initial lesion appears after inoculation is due more, if not entirely, to its location with reference to the lymphatic vessels than to various grades of susceptibility by some supposed to exist in the individual. This is also especially true as regards the length of the interval between the appearance of the chancre and the onset of secondary symptoms.

4. *Is there a decided interval between local and systemic infections?*

An affirmative answer to this question will be gainsaid by no one. An intermediate manifestation, however, is apparent between these local and general disturbances, and it shows itself in the first set of lymphatic glands reached by the lymphatic vessels beginning at the seat of inoculation. The time at which these glands show evidence of participation in the syphilitic process varies. Enlargement may commence shortly after the formation of the primary lesion or within a brief period before the onset of general secondary symptoms. There can be no doubt, though, about there being a distinct interval between local and general infection. The action of the lymphatic glands leads to the next question.

5. *By what channels does the disease enter the system—by the blood or by the lymphatics?*

By the blood?—When we consider the rapidity with which the blood flows through our bodies, and the uniform results obtained in producing rapid effects by intra-sanguineous injections, it is impossible to reconcile these well-established facts with the comparative exceeding slowness of general syphilitic infection, unless it be on one ground. This would be that a second incubation takes place in the blood analogous to that at the point of inoculation, or that the period of incubation of the virus in the blood is longer than that among the stable cells; but this would be contrary to all known physiologic laws and processes. Were the blood-vessels and their contents the distributing channels of this poison, the general infection of the patient would not be so long in taking effect, nor would it be interrupted. The blood is not the channel by which the virus enters the system.

By the lymphatics?—We all know, from the results of investigation in the physiological and pathological laboratories, as well as clinical experience, that the blood is the body's distributer of food and air in its passage from the heart, while on its return it renovates the tissues by the abstraction of those impurities that are the natural result of physiological metamorphosis. The lymphatics, on the contrary, among other things, perform an interceptive function in preventing or retarding the entrance into the circulating blood of those deleterious substances for the elimination of which there appears to be no special provision. Thus, although carbonic oxide and urea are very poisonous, they enter the blood to be promptly excreted, the one by the lungs and the other by the kidneys; there is a special provision for their elimination, as they are a normal, constant, and necessary product. Contrariwise, the virus of carcinoma is not the outcome of normal, constant, and necessary physiological activity, but the result of changes that are abnormal, inconstant, and decidedly unnecessary, and hence has not provided for it a special and normal eliminative organ. If it once enters the blood, it will remain and spread disaster. It only gets there insidiously. The blood does not take it up. Lymphatic vessels which ramify throughout the body and lymph-spaces existing in nearly all the tissues absorb this product of unusual and abnormal metamorphosis and conduct it to the first set of lymphatic glands. Here it is retained as long as the gland is capable of holding it, and, when this retentive function becomes inefficient, the poison passes into the blood, and the general infection of the individual is the immediate and inevitable result.

It is through the lymphatics, then, that syphilis enters the system, although retarded in its progress through the glands.

6. *Can the progress of the virus be traced from the time and place of entrance into the tissues until general infection has occurred?*

This is possible, and it occurs in the following way:

As soon as the poison comes in contact with the living cells it sets up an irritative process, which, in consequence of its persistence and special qualities, eventuates in the peculiar cell proliferation that gives rise to the initial lesion of syphilis. This cell formation is peculiar in that it involves the vessel-walls, causing them to grow eccentrically as well as concentrically, thus giving rise to an increase in their external diameter coincident with a diminution of caliber. Many detached cells and nuclei are to be found within the lumen of the capillaries obstructing the flow of blood. The immediate fixed connective-tissue cells also participate in the proliferating process, and to such an extent that the intercapillary spaces become packed with these new formations. In consequence of the diminished caliber of the vessels, there is an absence of the degree of hyperæmia so common in pathological cell formations. Serous effusion is also lacking on account of the scanty blood-supply and the thickening of the vascular walls. Those compacted cells which are on and nearest the surface, being enabled to imbibe their nourishment from all directions except one, die and fall off from this side—that is, die at the surface. Considerable pressure is exerted within this cell accumulation and causes the contained serum to find its way out through

the surface breach, in which direction evidently is the least resistance. The induration of this, the chancre, is due to the close packing of the cells, the lessened blood-supply, and the spare amount of serous effusion. The long continuance of the induration after it has healed over is also accounted for by the diminished local circulation and abnormal condition of the vascular walls as being a decided interference in carrying on any absorptive process.

The lymph-spaces and vessels in contact with these new products absorb the virus and convey it to the nearest lymph-glands. Here the virus is arrested and tends to set up a process identical with that existing at the place whence it just arrived. Eventually this is accomplished as well as it is possible in a different tissue. The result is an enlarged and indurated gland. We all know, too, how hard are these glands and how hard is the chancre. The typical primary sore does not really suppurate, for it simply throws off superficial layers of cells and *débris* with a limited amount of modified serum. A fact that is interesting to note now is that the glands involved, although enlarged and indurated, rarely suppurate.

The production of leucocytes constitutes one of the functions of lymphatic glands, and from them the white corpuscles are at once admitted to the circulating blood. It is evident from this that, after a brief residence in these glands, the poison will be admitted to the blood and pervade the whole body. The glands, however, as a rule, either destroy the virus they have brought to them, or render it innocuous, but not in all instances. It is hardly necessary to remark that in the case of syphilis we have a notable exception to this rule, but not without compensatory action of the gland—to wit, the retention of the virus for a sufficient length of time to admit of its mechanical removal. When the virus has penetrated those parts of the glands which are about to be launched into the circulating blood, the first step toward general infection has been taken. Additional loads of virus are thereafter constantly being thrust into the circulation and carried by it to all parts of the body. The other lymphatic glands being more susceptible to the influence of this and similar poisons than any of the other tissues, it is but natural that a general glandular disturbance should note the beginning of secondary symptoms, and that is actually what occurs in most instances. That the more superficial glands should be the ones mentioned as being enlarged at this time is only natural, for the deeper ones are not felt by the physician. Therefore does it happen that we are usually told that the cervical and supra-trochlear glands are the ones most commonly found enlarged at, or just preceding, the onset of secondary symptoms.

When we consider that of all disorders, excepting phthisis, there is probably none that is so malign in its effects upon our species as syphilis; when also we regard the fact that a very large proportion of the victims of this affection are a prey to heredity; and when, lastly, we reflect upon the present utter impossibility of preventing a general systemic syphilitic infection, and that too in defiance of valuable palliative medicinal resources—I say, then, it must be admitted that any therapeutic measure that may be proposed for the eradication of syphilis previous to systemic infection is justifiable, if based on rational grounds. Not only is it justifiable, but it is unmistakably our duty to attempt these means if they give a reasonable promise of success.

In the light of established facts, it is hard to believe that well-informed men still exist who will not admit the purely local nature of the chancre and resulting enlargement of the nearest lymphatic glands. It is a widely known fact that a person having syphilis is unable to develop a second primary lesion so long as he gives evidence of existing constitutional infection. Less widely known is the equally well-established fact that additional chancres may be developed *ad libitum* up to a short time before the outbreak of symptoms denoting constitutional infection.

In fact, the strongest claim for the curability of syphilis is based upon this very fact of a person with general symptoms being uninoculable with the same disease. He enjoys absolute immunity from additional infection, and must be cured to be at all susceptible of reinfection and the development of a second chancre after having once suffered constitutional syphilis.

If this is the correct view, and surely it is the most reasonable one, it is equally as certain that constitutional syphilis does not exist up to a short time before the secondary eruptions, because a second chancre or series of chancres may be developed either by auto-inoculation or hetero-inoculation during this particular period.

In the treatment of any disease, it should be our first effort to attempt its abortion, and of none can it more truly be said that such attempt is our first and imperative duty than syphilis. Complete excision of all the structure harboring the virus while it is still local would positively abort the disease. At present it appears that the chancre and nearest set of lymphatic glands are the only structures affected during this primary period. Their thorough excision promises to effect the immediate termination of the disease, if accomplished sufficiently early. I should call sufficiently early any time previous to the appearance of secondary symptoms, and while the glands were still not much enlarged. All measures of this kind would be, however, absolutely contra-indicated after the outbreak of the secondary stage.

As regards the mode of operating, I think one thing very important and essential to success. It is that, inasmuch as glandular infection is due to material coming from the chancre, the safest way would be to remove the primary sore first and the glands afterward. Then, again, as the virus traverses gland after gland in regular order, reaching the one farthest removed after it has affected the nearer ones, it would be most safe to begin the glandular excision with the removal of the most distant one first and ending with the nearest and first affected.

I recognize at once one possible source of failure in this treatment, and that is that some of the virus may be retained in the lymphatic vessels between the excised sore and glands and permit of its absorption through collateral channels. This is guarded against, as far as possible, by the elimination of the active source of infection, the chancre, before the absorbents are cut off from their receiving

glands. Perhaps it would be well to allow several hours to elapse between the excision of the sore and of the glands, so as to admit of the convergence of all the virus in the lymphatics to the glands about to be extirpated. Or, best of all, it would be most advisable to excise all the lymphatics between the chancre and glands if at all affected, and possibly it would be still better to always excise these vessels, whether they appear to be affected or not.

Only clinical experience and experimental research can, however, positively settle this point, and it is for the purpose of gaining this valuable experience as soon as possible that I have thus early offered this paper. If every man will cast aside his prejudices and attempt this abortive treatment of syphilis, we shall soon see demonstrated the fallacy or correctness of this view. That it will prove correct I have not the least doubt. It is only necessary to cast our eyes about and note the increased percentage of cures from carcinomatous excisions, since complete extirpation of the whole set of lymphatic glands nearest the neoplasm has come into vogue, to gain hope and confidence for the method of cure herein advocated. These glands, be it remembered, in operations for carcinoma, are thoroughly excised, although very often without the slightest evidence of disease. We have but to recollect the character of syphilis and its associations to feel the deepest commiseration for the innocent progeny who inherit the disorder. For this reason alone, if for no other, every rational means ought to be tried, and is justifiable, to prevent its spread not only around us but to future generations.

Perhaps many former advocates of chancre excision will be opposed to this abortive plan of treatment because of the almost generally conceded failure of that half-way therapeutic measure. Yet even this method may be all that is necessary in rare instances where the glands have not yet received any of the virus. I am willing to believe that some of the reported cases of cure in this way were actual instances of aborted syphilis. It is to be hoped, therefore, that those gentlemen who once championed chancre excision, and, of course, those who do so still, will be the first to take in hand the practical testing of the more thorough method it seems to me so proper to advocate.

Deeming the foregoing sufficient an outline to subserve the purpose of creating intelligent discussion on this question, I will complete my remarks with a few additional statements.

My object has been to be fair and temperate in all that has been said. Although readily admitting plenty of room for honest differences of opinion in more than one part of my argument, I have refrained from attempting a systematic refutation of everything that seemed inconsistent from my standpoint, as it would only have interfered with the real objects of this paper. It is also well to recollect that the deductions I have made are based on the *rule* of behavior in syphilitic processes and their manifestations. Exceptions to these general rules in the clinical history of this disorder are many and various, yet, if thoroughly analyzed, will be found to have no confuting effect upon the preceding argument. Even this, though, is only a rule, and also may have its exceptions, and exceptions, be it remembered, are often proof that rules exist.

I have been as general as possible in the treatment of this question instead of being more specific, so that it should have the widest application and be followed by the broadest and most profitable discussion. The failure to mention the names of authors, or relate interesting and important experiments and cases, must not be construed in any other sense than that the object was to avoid undue complexity and to save time. The great and only point at issue in the discussion of this question is, How soon after inoculation does systemic infection occur?

In the hope that the discussion of this question will be frank and constantly to the point at issue, I have the honor of submitting to your judgment this argument on the early and prompt eradication of syphilis for all that it is worth.

IMMUNITY IN DISEASE.

By ROMAINE J. CURTISS, M. D., Joliet, Ill.,
PROFESSOR OF HYGIENE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

The paper read by Dr. R. G. Eccles before the Brooklyn Pathological Society, and published in the "New York Medical Journal," May 23d, refers to a subject which must eventually be settled. People will never be contented with the phenomena of disease, in relation to the causes, without a generalization which will cover the whole group of phenomena. The hypothesis of gravitation and that of the existence of a light-ether explain the phenomena of the universe relating to the motions of the spheres, and also the phenomena of light. What gives immunity in disease, what causes disease, and how do the causes act? are leading questions that must all be grouped together under one generalization which can explain them all, and I take it that any contribution looking to this end will be welcome to the profession.

Before proceeding to actual work, it may be useful to examine the methods of doing this particular kind of work —to get the tools in good working order. I believe it is understood that whatever classes, orders, or varieties of things or phenomena we are studying—whether they be affairs of common life, or any special science, or whether the most complex questions that confront the philosophers—one of the objects of our study is to generalize laws from the things or phenomena, and the method or tool with which we work is hypothesis. It is a "cut-and-try" method. The hypothesis is designed to occupy the place of a general cause or antecedent to the whole group of questions under consideration. In selecting an hypothesis, care is required to be certain that the selection is a real cause in Nature, or else can be proved to be, and, when the selection is made, it appears that we have the question to settle next that the hypothesis is capable of causing such results as we are studying, and at the same time it must be proved that other supposed causes, or hypotheses, are not sufficient.

I think this is a fair conception of the method employed in the study of all things and phenomena, including disease; and now, before proceeding further, it is necessary to define what is meant by immunity from disease.

This inquiry being limited to the zymotic diseases, the meaning of immunity from disease must be that the organ-

ism can by some means resist the living agent of disease. The power of resistance, whatever it may be, is acquired, as we certainly know, by an attack of the disease; and it is known that this power is also acquired by heredity. A person may be exempt from the attacks of given species of parasites, by reason of a former battle with the same species, or a variety of the same species, or the person may have immunity from the successful attacks of these enemies which he obtained by heredity from a long line of parasite-pestered ancestry.

Unless it can be proved that people inherit the actual germs of disease, the law of heredity must impose the inference that, instead of inheriting a disease, persons inherit an immunity from disease, or else fail to inherit the immunity. The heredity of disease would appear to be negative—that is, a person inherits the disease simply because he fails to inherit an immunity. This view of the question of heredity will fully explain the fact that consumptives and syphilitics and the victims of other hereditary diseases are the victims of these diseases because their ancestors have not acquired, by natural selection or by actual combat with the infectious causes, an immunity from the diseases.

We know very well that immunity from such a disease as small-pox in an individual is acquired by an actual combat with the infectious cause of small-pox. The inference must follow, therefore, that the people who escape the zymotic diseases, by reason of personal immunity or by reason of a successful vital or physical resistance to the germs, do so not because they have failed to encounter the germs or failed to inherit them, but because they have inherited the physical resistance from ancestors who acquired the same by reason of having the disease.

But we find that immunity from disease has quite indefinite relations to time. In a certain ratio the immunity lasts a life-time, but in a far larger ratio it lasts for only a year or a few years. Probably, if an average could be known, it would be found that seven or eight years would express it. Now, whatever the immunity may be, it is evident that it is not lasting enough or forcible enough, in more than a small ratio of cases, to make much impression on hereditary transmission. Suppose one hundred people have small-pox; possibly out of this number there might be twenty instances where the immunity would be powerful enough to cause more or less impression on the forces of heredity.

The two great forces of the development of all organisms are atavism and variability. Development is a resultant of these two forces. Behind them both are the most complex antecedents pertaining to the struggle for existence; but these complex antecedents, grouped as they all are under two heads, all converge into the two forces which we understand as atavism and variability. The character of human development, from the mental and moral peculiarities to even the color of the skin and the stature of the man, must be referred to the interactions of these two forces for a solution, and we must look to these things also for a solution of the problem of immunity from disease.

From these data there is no better inference than the hypothesis that an actual attack of pathogenic organisms produces a variation of structure, the character of the variation and the structure subject to the variation being determined by the nature or method of onslaught and the tissues or cells that are attacked. Following up these special lines, we find that different pathogenic organisms attack different portions of the body, and that the method of warfare is by poisons.

To fortify this hypothesis it may be mentioned that living things which are adapted to each other as a food-supply must kill each other or catch each other first, and I think the two methods of causing death are by mechanical means and by poisons. Animals use stratagem, speed, tooth, beak, claw, muscles, and poisons, while the pathogenic bacteria use poisons. The micro-organisms, it is supposed, absorb their diet by osmosis, and it can not be imagined that this force of absorption can overcome the vital or physical integrity of a tissue-cell, and therefore the inference is that, if the cell resists the absorptive force of the micro-organism by its quality of life, it must resist the poison of the same agent by a variation of its vital or physical power of resistance, which is acquired by actual combat.

If the ancestor of the antelope was given an occasional chase by a personal enemy—for instance, a wolf—and succeeded in escaping, no one will dispute the fact that the antelope obtained its speed by such means, and transmitted this quality to its progeny. The difference in speed between the ancestor of the antelope and the modern species is the measure of the variation produced by actual combat with a personal enemy. The struggle for existence of this special character caused this variation. If a whole herd of wolves should now be turned into an inclosed lot with an antelope, it is quite likely that the antelope would fall a victim, but this would not disprove the fact that in a state of nature the speed of the antelope was developed in this manner, and that nature, or natural selection, by this means has preserved the antelope as a species. This bit of biology explains a special instance of the law of variability. But now, suppose the species of wolf is destroyed; the force behind this variation is removed; the antelope has no care to exercise its speed, and gradually loses its power, and, in time, by what is called atavism, it again resembles, in this respect, its ancestor.

The pathogenic bacteria are organisms of prey, and a disease is simply a combat between the cells and the organisms which are there after food. It is difficult or impossible to say how a poison may destroy a cell, but it is certain that the effect of the poison is to destroy life, and such is its object. If it is true that disease is thus caused by destroying the life of cells, then it is true that immunity may be aequired by a variation of the cell in structure or function, so that it may resist the poison. The question of drug-tolerance by cells is established by experiments with morphine, alcohol, etc. There is no scientific method of explaining this fact except by the inference that a variation in structure and function is produced in the cell as a consequence of actual combat with the poison. The cell may secrete an antidote to the poison of the enemy, or its molecular elements may be rearranged in such a manner that the poison is not effective. Either of these propositions may do as an hypothesis, and, though they may be difficult

to verify, they are true *veræ causæ* in nature, and they can explain the phenomena of the immunity from disease, singly and collectively.

Suppose, now, the cause of disease is removed; the cells which have acquired a variation of structure or function, by the law of atavism, lose this variation. In time the immunity ought to run out, and we find this to be true. The immunity from, or protection given by, one attack of disease varies, in time, in direct proportion to the severity of the disease, as a rule. There is no other method of explaining this phenomenon except by these laws of variability, atavism, and natural selection.

The artificial tests for the protection thus afforded against disease, which consist in injecting a large quantity of pathogenic bacteria into an animal which is sufficiently protected to resist the attacks of disease by natural invasion, resembles the method mentioned of testing the protection given the antelope through its speed by exposing it to a pack of wolves in an inclosure. The conditions of nature in these instances are not imitated, and, consequently, no information of value can be inferred from such experiments.

(*To be concluded.*)

Book Notices.

A Practical Treatise on Nasal Catarrh and Allied Diseases. By Beverley Robinson, A. M., M. D. (Paris), Clinical Professor of Medicine at the Bellevue Hospital Medical College, etc. Second Edition, Revised and Enlarged, with One Hundred and Fifty-two Wood Engravings. New York: William Wood & Co., 1885. Pp. xii–276.

Those who were so fortunate as to read the first edition of this excellent work will hardly recognize it in the elegant second edition now before us. To the book as it first appeared five chapters have been added. These are devoted to the study of: 1. Aural Complications of Catarrhal Affections of the Nose. 2. Deflections of the Nasal Septum and Bony Obstructions of the Nasal Passages. 3. Ulcerous Coryza. 4. Adenoid Vegetations at the Vault of the Pharynx. 5. Mucous Nasal Polypi.

The text of the original edition has also been carefully revised, and changes or additions made where required, while ninety-six illustrations have been added, and the work made complete up to the date of its issue. Want of space forbids the extensive review which should be given it. There is much in it which deserves commendation, and every evidence of experience in the use of the methods advised and of painstaking care in their presentation.

The main fault of the author is an undue redundancy of style, which adds unnecessarily to the length of his chapters without in any wise contributing to their clearness.

Among the cuts the reader will recognize the familiar face of many an old friend. Figs. 26 and 27 might well have been omitted.

Compared with the substantial merit of the work, however, these are trifling matters. It will be difficult to find in any language a more exhaustive and thorough treatise upon nasal catarrh, so that the book should, and we believe will, have a wide circulation

Post-Nasal Catarrh and Diseases of the Nose causing Deafness. By Edward Woakes, M. D., Senior Aural Surgeon and Lecturer on Diseases of the Ear, London Hospital, etc. Illustrated with Wood Engravings. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. 224. [Price, $1.50.]

This is an American reprint from the third English edition. The first chapter is devoted to some observations on the correlating and reflex functions of the sympathetic nervous system. Then follow two chapters on the Ætiology of Acute and Chronic Catarrh, in which are considered what Woakes calls the "pre-catarrhal state," and the mechanism of "taking cold." The chapter on the Hygienic Management of the "Catarrhally Predisposed" is full of useful hints and suggestions. The difficulties and importance of posterior rhinoscopy are well emphasized, and a most excellent account is given of the method of anterior rhinoscopy. There have been so many additions made to the original work that the English publishers thought it wise to issue the new matter in a volume by itself, and this is what is presented to the medical profession. It is a most clear and valuable contribution to our hitherto rather defective knowledge of diseases of the naso-pharynx. Some of the author's views will certainly not be accepted without careful consideration and repeated observations; but those on therapeutics will meet with cordial commendation.

A Hand-book of the Diseases of the Eye and their Treatment. By Henry R. Swanzy, A. M., M. B., F. R. C. S. I., Surgeon to the National Eye and Ear Infirmary, etc. With Illustrations. New York: D. Appleton & Co., 1884. Pp. xv–437.

Mr. Swanzy has here given to the medical student and general practitioner a most admirable hand-book upon what is perhaps the most important and extensive of the special departments of medicine. The author, who, as a former assistant to von Graefe, has been brought up in an admirable school and whose experience has been very large, treats his subject in a very thorough manner, while the style is readable and clear. There is a minuteness of detail in regard to treatment which will prove especially attractive to the student. The book consists of twenty-two chapters, the first three of which are devoted to elementary optics, anomalies of refraction and accommodation, and the theory and use of the ophthalmoscope. Under the latter head there is a full and excellent account of the method of determining the refraction by the ophthalmoscope known as "retinoscopy," now much employed in England. A special chapter is devoted to a consideration of the motions of the pupil in health and disease, which is a concise and admirable discussion of a subject of great importance to the general practitioner as well as to the ophthalmologist. Under this head we find both irritation- and paralytic-myosis, and irritation- and paralytic-mydriasis. This is prefaced by a consideration of the size of the pupil in health, and of the action of mydriatics and myotics on the pupil. A new feature in ophthalmic literature is to be found in the insertion upon the inner side of the cover of a set of Holmgren's wool-tests for the detection of color-blindness. The book is extremely well printed with clean, sharp type on tinted paper, and the illustrations are excellent. As a specimen of the book-maker's art, it is admirable.

A Hand-book of Ophthalmic Science and Practice. By Henry E. Juler, F. R. C. S., Junior Ophthalmic Surgeon to St. Mary's Hospital, etc. With One Hundred and Twenty-five Illustrations. Philadelphia: Henry C. Lea's Son and Co., 1884. Pp. 467.

Of the making of books on ophthalmic science there seems to be no end; but very little fault will be found by any one

with Mr. Juler's contribution to the library of ophthalmological text-books. It is a handsomely printed volume of about four hundred and fifty pages, well illustrated by plain and colored drawings and numerous colored lithographs of the fundus of the eye in health and disease. Some of the plates representing pathological processes in the cornea, iris, and ciliary body are particularly good. The book consists of sixteen chapters, to the arrangement of which in their order of sequence some exception may be taken. There seems no very good reason why the crystalline lens, the vitreous humor, and glaucoma should be considered after the subject of color-vision and its defects, nor why the chapter on Diseases of the Orbit should be placed last. It is much to be regretted that in the chapter on Conjunctival Diseases the author does not clearly distinguish between membranous and diphtheritic conjunctivitis, instead of classing them under the same head. They are two distinct diseases, and should not by any means be confounded. It may be said that ophthalmic surgeons, at least on this side of the Atlantic, are almost unanimous upon this subject. Due prominence is given to Mr. Wolfe's operation by transportation of a flap without pedicle for correcting certain cases of ectropium, or lid defect. The chapters on the Visual Field, Color-vision, and Color-blindness, Anomalies of Refraction and Accommodation, and the Ophthalmoscope are good, but it is necessary to state that they are all written from the English standpoint, which differs in some respects decidedly from that prevailing in this country. The pathological work is mainly represented by the colored drawings, there being very little in the text. The importance of the ophthalmoscope as a means of measuring the refraction is well stated, and there is a very good description of the method known as retinoscopy, or the shadow test, which, however, can be employed only by the practiced expert. In the chapter on Diseases of the Muscles the author prefers Anderson Critchett's operation for advancement of a muscle.

Notes on Operations on the Eye. By Ram Kishen, L. M. S., Lahore, Assistant Surgeon. Lahore: Printed at the "Tribune" Press, 1884. Pp. 2–ii–78–iii.

This little duodecimo volume of about eighty pages is by a native of the Punjab, and, as the author says in the preface, is an attempt to draw attention to the practical points in connection with the principal operations in ophthalmic surgery. There are no illustrations, and the English is awkward and at times verging on the ludicrous. The operations are, however, sufficiently well described.

A Guide to the Diseases of Children. By James Frederick Goodhart, M. D., F. R. C. P., Assistant Physician to Guy's Hospital, and Lecturer on Pathology in its Medical School, etc. Revised and edited by Louis Starr, M. D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania, etc. Philadelphia: P. Blakiston, Son & Co., 1885. Pp. 738. [Price, cloth, $3; sheep, $4.]

The special design of this book, the author tells us in his preface, is to furnish to medical students a manual for ready use in this department. A careful examination of the book will convince any one of the fact that he has succeeded admirably. We predict that its use will not be limited to students, but that the practitioner will find it convenient, trustworthy, and extremely suggestive upon most of the practical questions which it discusses. It is pre-eminently a book written out of the author's personal experience. Every page bears witness to the fact that he has been a wide and careful observer. The book is written in a readable, forcible style, and the points are clearly stated. The author possesses the rare faculty of condensing minor details and bringing out salient points vividly. Being at the same time a teacher in pathology, he has not neglected that branch of his subject, although the size of the work has made it necessary to condense very much.

When there is so much to praise, it is not easy to say which parts of the book are the most valuable. The articles on whooping-cough, empyema, scarlatina, and diphtheria are especially good. The author holds that the last-mentioned is distinct from membranous croup, but states that this distinction must rest on clinical and not on histological grounds. His treatment of empyema is by early evacuation, preferably by incision, although he says other means may be tried in some cases. He reports twenty-six cases treated consecutively, with but a single death. We can not quite agree with him that there is no advantage in distinguishing between the two forms of acute pneumonia.

There are many minor matters in which the book might be improved, but its excellences are so many that they can be overlooked. On the whole, we consider the work one of the best of its kind that have appeared in a long time. It will undoubtedly demonstrate its right to existence.

The work of the American editor has been fairly done, but we should have been quite as well pleased with the book in its original form. He has avoided the error of too extensive additions. In the translation of the expressions of the British Pharmacopœia into those of the United States Pharmacopœia he has rendered a real service.

The Theory and Practice of Medicine. By Frederick T. Roberts, M. D., etc., Professor of Materia Medica and Therapeutics, and of Clinical Medicine, at University College, etc. With illustrations. Fifth American Edition. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. 1008.

Dr. Roberts's book is sufficiently well known to need but little reference to it. This is the fifth edition—an evidence in itself of its favorable reception by the profession. It is the text-book used in many of the medical schools in this country.

Since the last edition the author has revised his work throughout, and has incorporated the results of discussions which have taken place since the appearance of the last edition in so far as they seemed of practical importance. He has paid special attention to diseases of the nervous system in this edition.

He discusses Koch's theories on the *Bacillus tuberculosis*, and gives a plate of illustrations of the bacillus. He does not commit himself to a positive opinion, but closes his discussion of this subject with the following significant remark: "It would be premature at present to come to any positive general conclusion on the subject; but there seems to be no doubt as to the possibility of tuberculosis being developed by infection from within and from without under certain circumstances." The discussion on the cholera bacillus had not taken place at the time this edition was issued. The author has here, as in previous editions, included skin diseases, which seems odd, at least to physicians in this country.

The work is an admirable one, and fully deserves the excellent reputation it has gained both as a text-book and as a safe and reliable book for the practitioner.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, JULY 11, 1885.

THE RUMP CONGRESS OF 1887.

It was scarcely to be expected that those eminent physicians of Philadelphia whose action in regard to the organization of the Ninth International Medical Congress we recorded last week would find themselves alone in the resolve to stand aloof from a gathering which, as is constantly growing more and more manifest, will be an international congress only in name. As will be seen by our news columns, Boston and Baltimore have promptly followed suit, and, like the Philadelphia resolutions, those passed in Boston and Baltimore are signed by men whose names are indissolubly connected with American medicine. Whether organized action of like significance will be taken in New York and elsewhere, it is impossible to say, but this much is certain, that some of the New York men whom the new committee of the American Medical Association placed among the officers of sections have no sympathy with the ostensible motives—far less with the real motives—which led a little band of malcontents to plot the destruction of the Washington meeting. Even if those gentlemen do not formally express their feelings in the matter, there can be no doubt that they will abstain from any participation in the Washington meeting.

It looks, indeed, very much as if the part of Hamlet would be left out at Washington in 1887, for our foreign colleagues will in all probability decide not to cross the Atlantic in any great numbers for the pleasure of meeting the rump of the American profession. And all this disgrace is the logical outcome of the false and artificial issues which for the past three years have enabled men in no way representative of the profession to masquerade as its leaders, through the medium of that degenerate and utterly ridiculous concern the American Medical Association. That organization long ago ceased to work for the benefit of the profession, and for a number of years past its annual meetings have been little more than scenes of the most shameless intrigue and demagogism. From the nature of its make-up, and from the character of the men who manipulate it year after year, the hope is exceedingly untenable that, within any reasonable period, this state of things will be mended. It has made itself as odious as any board of aldermen in the land, but, unfortunately, it is so intrenched in jugglery that to draw its fangs is almost as unpromising a task as that of uprooting municipal misgovernment. Difficult as this task is, however, its accomplishment is only a question of time, and it is even now evident that, for at least five years past, the association has owed its continued semblance of life to the force of the familiar politicians' plea that, whatever its shortcomings might be, it was, after all, the only organization of a national character that professed to be in any way representative of the whole profession. If its hangers-on think that its steady degradation is for ever to be condoned on the strength of this plea, we would point them to what lately happened to one of the great political parties of the country. The plea amounts to this, that anything which the American Medical Association chooses to do is better than no concerted action at all. How long this specious cry is likely to prove potent may be judged of from the fate which, in the history of the world, has uniformly overtaken organized villainy sooner or later, no matter what its seeming power, and no matter how white its hypocritical cloak.

The crowning act of infamy in the downward career of the American Medical Association has been achieved in the wrecking of the American meeting of the International Medical Congress, a meeting which, but a year before, it had seemed to be doing its best to make creditable and successful. Doubtless it may be said with truth that the action it took at New Orleans is not in consonance with the deliberate convictions of the great mass of its members, but that consideration is in fact a most telling arraignment of its methods of dealing, for an organization which fails year after year to bring out the real sentiments of its members falls conspicuously short of the aims it ostensibly has at heart.

That the wreck of the Congress of 1887 has not been irretrievably wrought we can now see no reason to hope. It is, of course, not to be supposed that the Congress will formally reconsider its acceptance of the invitation extended to it by the American profession, but the conclusion can scarcely be avoided, nevertheless, that the European members who would add luster to the gathering will individually make up their minds not to attend the meeting, and it will simply go by default.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 7, 1885:

DISEASES.	Week ending June 30.		Week ending July 7.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	13	4	13	4
Scarlet fever	29	7	35	5
Cerebro-spinal meningitis	1	1	4	4
Measles	100	25	56	12
Diphtheria	63	35	41	21
Small-pox	0	0	3	0

Yellow Fever.—A single case was reported to the New Orleans Board of Health by a physician last Saturday, and two inspectors confirmed his diagnosis. The patient was convalescent at the time, and we have no information of the spread of the disease.

Small-pox.—An Astoria physician encountered a case of small-pox at Hunter's Point last week, and at once notified the sanitary officials of Long Island City, who, however, seem to have been in no haste to adopt measures for the protection of the community. Early this week a case was discovered in New York, in the upper part of Fourth Avenue. The patient, a child, was removed to the Riverside Hospital.

The International Medical Congress and the Medical Profession of Boston.—At a meeting held in the Medical Library Building, in Boston, on July 2, 1885, the following resolutions were unanimously adopted:

Whereas, We had been led to believe that the authority to organize and control the Ninth International Medical Congress had been permanently delegated by the American Medical Association to its original committee, thus providing against any radical changes in its published programme; and

Whereas, The American Medical Association has revised the action and annulled appointments of that committee in a way which we regard as detrimental to the interests of the medical profession of Ameriea and fatal to the success of the Congress; therefore be it

Resolved, That we, the undersigned, members of the medical profession in Boston and vicinity, concerned in the organization of the Ninth International Medical Congress, decline to hold any office in said Congress as now organized.

Robert Amory,	R. H. Fitz,
G. M. Garland,	Thomas Dwight,
H. P. Bowditch,	C. J. Blake,
R. T. Edes,	J. C. Warren,
J. J. Putnam,	O. F. Wadsworth,
Francis Minot,	S. J. Mixter,
J. R. Chadwick,	F. I. Knight,
C. F. Folsom,	G. H. Lyman,
Hasket Derby,	Jacob L. Williams,
S. G. Webber,	H. W. Williams,
T. M. Rotch,	H. P. Walcott,
T. Fillebrown,	J. Orne Green,

E. Wigglesworth.

The International Medical Congress and the Medical Profession of Baltimore.—In consequence of the dissatisfaction caused by the recent action of the new Committee on the Organization of the Ninth International Medical Congress, the subjoined paper has been signed by those whose names are appended.

Whereas, The new Committee on the Organization of the Ninth International Medical Congress, at its recent meeting, held in Chicago, made such changes in the arrangements for the Congress as, in our opinion, will mar its success, and will prove injurious to the interests of the medical profession, it is therefore

Resolved, That we, the undersigned, disapprove of the action of the committee, and decline to accept the positions to which we have been appointed under it:

I. E. Atkinson,	Richard McSherry,
S. C. Chew,	F. T. Miles,
Julian J. Chisolm,	Alan P. Smith,
Christopher Johnston,	Samuel Theobald,
William Lee,	L. McLane Tiffany,
John N. Mackenzie,	H. P. C. Wilson.

The New York Post-Graduate Medical School and Hospital.—Dr. Horace T. Hanks has been elected professor of diseases of women, and Dr. Lewis S. Pilcher professor of clinical surgery.

The New York Polyclinic.—The "Journal of Comparative Medicine and Surgery" announces that the faculty of the Polyclinic, of which Dr. Frank S. Billings is a member, has consented to his teaching special classes of veterinarians in the pathological laboratory of the institution.

The Water Supply of Manhattan Beach having been made the subject of complaint, the local health officer, Dr. R. L. Van Kleek, has caused an examination of the water to be made, and reports that it is of good quality.

The New Hospital for Infectious Diseases, on North Brother Island, is nearly ready for occupation, and it is expected that the Riverside Hospital will soon be abandoned.

Cremation in Buffalo.—It is announced that a crematory is soon to be built near the cemetery in Buffalo, the incinerating apparatus for which is to be made in Milan, Italy.

The Glasgow Obstetrical and Gynæcological Society.—Our English exchanges announce the organization of a society with this title in Glasgow, with Professor Leishman for president.

The Royal Academy of Medicine, of Rome, according to the "Lancet," has admitted the British delegates to the recent International Sanitary Conference, Sir Guyer Hunter, Dr. Thorne Thorne, Sir Joseph Fayrer, and Dr. T. Lewis, as honorary fellows.

The Death of Dr. Joseph Estabrook, of Rockland, Me., took place last Sunday. The deceased was eighty-seven years of age, and is said to have been the oldest graduate of Williams College at the time of his death. He was an alumnus of the Harvard Medical School. Many years ago he was the demonstrator of anatomy in the Medical School of Maine, and had been president of the Maine Medical Association.

The Death of Dr. G. B. Soresina, the distinguished Italian syphilidologist, is announced in the "Gazzetta degli Ospitali." The deceased was eighty-three years of age.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 28, 1885, to July 3, 1885:*

Ainsworth, F. C., Captain and Assistant Surgeon. Relieved from duty at Headquarters Department of the Missouri. S. O. 93, Department of the Missouri, June 26, 1885.

Taylor, B. D., Captain and Assistant Surgeon. Assigned to duty at Little Rock Barracks, Arkansas. S. O. 139, Department of the East, July 1, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the two weeks ending July 4, 1885.*

Bransford, John F. Commissioned as surgeon on active list. June 16, 1885.

Ross, J. W., Surgeon. Detached from Naval Laboratory, and waiting orders. June 30, 1885.

Shafer, Joseph, Assistant Surgeon. For duty on board the U. S. Receiving Ship St. Louis, League Island, Pa. July 10, 1885.

Society Meetings for the Coming Week:

Monday, *July 13th:* Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

Tuesday, *July 14th:* Medical Societies of the Counties of Clinton (Plattsburg), Jefferson (Watertown), Madison, Oneida (Utica), Ontario (Canandaigua), Rensselaer, Schuyler, Tioga (Owego), and Wayne, N. Y.; Norfolk District, Mass., Medical Society (Hyde Park).

Wednesday, *July 15th:* New Jersey Academy of Medicine (Newark).

Thursday, *July 16th:* New Bedford, Mass., Society for Medical Improvement (private).

Letters to the Editor.

THE MEDICAL PROFESSION IN CINCINNATI.

Cincinnati, *July 3, 1885.*

To the Editor of the New York Medical Journal:

Sir: In your issue of May 30, 1885, page 608, appears a "Letter from Cincinnati," upon which I ask permission to make comment. Some of its statements are unjust to the medical societies and profession of Cincinnati. For the sake of brevity, I condense some paragraphs from the letter and place them in relation without special regard to their order in the letter.

"About ten years ago Dr. Reamy, then a new comer, made the declaration in debate in the Academy to the effect that there *were members of the Academy, in otherwise good standing, who were guilty of criminal abortion.* . . .

"Dr. R. was a member of the faculty of the Medical College of Ohio; his immediate antagonists were of the faculty of the Miami Medical College. The third party, the Cincinnati College of Medicine and Surgery, kept its hands off and watched the fun." . . . The vote came. Dr. R. was vindicated. "The Miami people said, No man can maintain his self-respect and remain a member of the Academy. They resigned and organized the Cincinnati Medical Society." . . . The feelings then engendered have succeeded in keeping many people from both the Academy and the Cincinnati Medical Society, for in that way alone was it possible to maintain friendship with both factions. The result has been a dearth of good matter presented at both societies, . . . "the generally meager attendance at the meetings particularly of the Academy and the Cincinnati Medical Society." . . . "The fact is that either animosity or apathy interferes with the popularity of both these societies." . . .

Comment.—1. Dr. Reamy's charge was in these words: "For we must not shut our eyes to the fact, known to us all, that there are members of the medical profession, in otherwise good standing, who sometimes commit abortions." The Academy of Medicine was not mentioned by the speaker.

2. Neither the gentlemen who introduced the resolution arraigning Dr. R. for his utterances, nor either of the three gentlemen composing the committee on ethics conducting the prosecution, were members of, or in any way connected with, the faculty of the Miami Medical College, nor have they since been so connected.

3. One of the most active members of that committee was for some time an able lecturer in the Cincinnati College of Medicine and Surgery. And the present professor of surgery in this same college was one of Dr. R.'s most earnest supporters during the controversy referred to. And one of the spiciest letters of the many received by Dr. R. during that controversy was written by the father of your Cincinnati correspondent, who was at that time one of the oldest and most active members of the Cincinnati College of Medicine and Surgery.

4. Though a new society was organized, and though many of those who participated in its organization had recently resigned from the Academy, there were many, and are now many, who are members of both societies.

5. The membership of the Academy is as large as before the organization of the new society. The average attendance at stated meetings is as great, the papers read, cases reported, and discussions thereof are as able, interesting, and instructive as at any period in its history. An examination of its recorded proceedings will prove the truth of this assertion. Many of the papers and discussions will compare favorably with the work of any similar society in the country.

6. Though the attendance at the meetings of the Cincinnati Medical Society is not quite so large as that of the Academy, as the membership is not so large, yet the attendance is good, and their papers and discussions merit the same commendation as above given to the Academy. Both of the societies are popular. Of neither can it be said that "there has been a dearth of good matter presented."

7. There is no bitter feeling held against the other by either of these societies. Nor is there any hatred between individual members thereof. Nor between the faculties of the Medical College of Ohio and the Miami Medical College.

8. The statement that "the active participants in the old fight are gradually retiring from the field of active practice, and are, fortunately, quite unable to leave their hatreds as a heritage to the new generation," demands the following reply: Two or three of the participants in the old fight have died. Of those remaining, every one is in active practice, some of them doing six times more professional work now than then. As to hatreds, they have none. Personal and professional friendships prevail between the leaders on both sides. It is true the fight was "acrimonious," but, as no personal issues were involved—only misunderstandings as to the application intended by Dr. R. in his original statement made in the Academy—it was quite natural that, after all was over, friendship should be restored; and it was. All this occurred without an apology or explanation being made by the former antagonists in any instance. The absolute obliteration of ill-feeling which has for years existed may be considered exceptional, and is certainly commendable to all parties.

It is the testimony of those who know best, that friendship, harmony, and good feeling never prevailed more supremely in the medical profession of Cincinnati than at present.

The impressions sought to be made by the letter of your correspondent are therefore unwarrantable, and demand contradiction.

But what prompted him? His intelligence is well known; that he wrote in malice toward any is not at all probable. That he would write what he knew to be untrue I do not believe. What then?

Residing and practicing in another town, he can not attend the meetings of the societies in Cincinnati nor mingle with the profession, and has therefore been misled as to his facts.

Very respectfully,

Thad. A. Reamy.

Proceedings of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of May 27, 1885.

The President, Dr. John A. Wyeth, in the Chair.

Epithelioma of the Tongue.—Dr. C. W. Knight presented a portion of the posterior part of the tongue, the seat of epithelioma, removed after ligation of the lingual artery.

Lipoma of the Back.—Dr. L. Waldstein presented the specimen, removed by Dr. Lange from a woman eighty-six years of age. The tumor was removed because of the presence of an ulcer of the skin which refused to heal. The specimen illustrated the fact that lipomas sometimes developed and did not become reduced in size in persons in whom there was marked emaciation.

Adeno-sarcoma of the Stomach.—Dr. Waldstein presented a second specimen of adeno-sarcoma of the stomach, of

the diffuse variety, located chiefly at the fundus and cardiac extremity. The patient, forty-six years of age, had suffered extremely during the last four months of life. There were large quantities of granular detritus from division of the nuclei which had sometimes been mistaken for micro-organisms. There had been marked jaundice, and a diagnosis of carcinoma of the liver was made, a tumor of the size of a pigeon's egg being mistaken for that disease. The autopsy showed the tumor to be the enlarged gall-bladder, the duct of which was partially obstructed by metastatic tumors of the lymphatic glands of the porta hepatis.

Diphtheritic Laryngitis.—Dr. Joseph E. Winters presented the lungs of a child nearly two years of age, which had died of exhaustion and asphyxia due to diphtheritic laryngitis. The disease had for some days been limited to the fauces, not involving the larynx for more than a week. When dyspnœa was present tracheotomy was proposed, but rejected by the father. The autopsy showed the presence of the exudate only for three fourths of an inch below the vocal bands. There were muco-pus and vascularization below that point. There was marked vascularization at the bases of the lungs, and in the anterior portion there was some degree of anæmia with unusual distension.

Dr. C. C. Lee asked Dr. Winters what had been his experience with Dr. O'Dwyer's laryngeal tube.

Dr. Winters said that, the tubes having been so generally discarded in France, he had not employed them.

Dr. Lee remarked that the tubes used in this city had arrested the progress of spasmodic disease and had saved lives where laryngotomy doubtless would have failed. He thought the tube might prove useful in cases of diphtheritic laryngitis by relieving dyspnœa when the parents would not consent to tracheotomy.

Dr. Northrup remarked that at the New York Foundling Asylum the tube had relieved urgent laryngeal symptoms almost immediately. He asked Dr. Winters whether in his experience the past season the false membrane had shown a strong tendency to extend downward into the bronchi.

Dr. Winters said that most of the cases which he had seen were consultation cases, and he thought that when treated early the membrane had not extended much below the larynx. He thought the tendency of the exudate to spread would be greater in institutions than in private practice.

Dr. H. J. Boldt said that, according to his experience during the past winter, the false membrane had shown a great tendency to extend below the larynx.

Dr. J. C. Peters had employed frequent irrigation of the throat and used bichloride of mercury in cases of false membrane upon the top of the larynx, and the patients recovered without extension of the membrane downward.

Pott's Disease; Necrosis of all the Principal Long Bones.—Dr. W. P. Watson, of Jersey City, presented the specimens, consisting of certain vertebræ, removed from the body of a child five years of age, which had died of pneumonia. The child had first developed a swelling over the right thigh, which was said to have entirely disappeared. Afterward there was curvature of the spine in the cervico-dorsal region, reaching a right angle, but at no time was there paralysis. Abscesses also developed over the thigh and both wrists, and exsection of a considerable portion of the right radius and of the right knee joint and lower portion of the femur was performed. At the autopsy there was found to be marked absorption of the fifth, sixth, and seventh cervical, and of the first and second dorsal, vertebræ. It was remarkable that but very little compression of the cord had taken place.

Frequent Recurrence of Pregnancy.—Dr. Watson also presented a fœtus of the sixth week which was aborted a few days after the repair of a bilateral laceration of the cervix uteri. The patient was an English woman of robust health, who had been pregnant seven times in six years, three being single and four twin pregnancies. Only two of the pregnancies went to full term. Menstruation had occurred less than a month before the cervix was repaired, and there was no reason to suspect pregnancy.

Multilocular Cystoma of the Right Ovary with Hydrosalpinx, and Cystic Degeneration of the Left Ovary with Simple Salpingitis.—Dr. R. W. Wilcox presented the specimens removed from a patient thirty-seven years of age, married, never pregnant. The enlargement of the abdomen had been observed for fifteen years, and during the last two years had been so great as to interfere considerably with locomotion. The patient was first seen by Dr. Wilcox in February last, when she was suffering from peritonitis pretty generally distributed, and from acute nephritis due to diuretics administered by her physician, who supposed her to be suffering from abdominal dropsy. There was no difficulty in making a diagnosis of tumor of the ovary. The nephritis subsided, and the peritonitis resulted in adhesions. Dr. Thomas performed ovariotomy. The larger tumor weighed a little more than forty-five pounds; the others were small. The tube was adherent to the tumor, elongated and atrophied, the uterine extremity occluded; there was distension with a clear yellow fluid. The left ovary had also undergone cystic degeneration, and the tube was adherent to it.

Thrombosis of the Left Coronary Artery; Interstitial Myocarditis and Dilatation of the Heart.—Dr. J. F. Ridlon presented the heart, very much enlarged, with thrombosis of the left coronary artery, of a man about fifty-five years of age, who had for some years suffered from dyspeptic symptoms with an interval of apparent good health extending over some months. About noon, April 30th, having been in his usual health, he felt distress in the stomach, and soon afterward became faint and vomited. He was seen by several physicians during the course of the afternoon and night, and at one time was supposed to be dead, but revived. The pain and restlessness were finally checked by a small hypodermic injection of Magendie's solution of morphine. The patient was able to walk to the fixed basin, which he insisted upon doing when compelled to vomit. At 7 A. M., May 1st, he seemed to be much better, but was found dead half an hour later. The most important lesions found post mortem were, as stated, thrombosis of the left coronary artery, completely obstructing its caliber, marked enlargement of the heart with dilatation, interstitial myocarditis, and fatty degeneration; there was also enlargement of the liver, spleen, and kidneys. The stomach appeared normal, but contained a few ounces of blood.

Intra-meningeal Hæmorrhage.—Dr. W. P. Northrup presented a microscopical slide, illustrating this condition. He also presented a

Section of a Lung embedded in Celloidin.—After finding that the ordinary processes were inadequate for the preparation of the entire lung for section, he placed the lung in a weak mixture of alcohol and water for some days, afterward in celloidin for a number of days, and finally again in alcohol. By this process he was enabled to make a complete section of the base of the lung. The section presented showed interstitial emphysema and in places pneumonic consolidation and infiltrated and dilated bronchi.

Multiple Abdominal Tumor.—Dr. C. C. Lee presented the specimen, removed from a quadroon, twenty-six years of age, of delicate frame, emaciated, who had observed an enlargement of the abdomen said by several physicians who had seen her not to be due to pregnancy. Dr. Lee diagnosticated tumor of

the ovary, although he had never seen a pure ovarian cyst in the negro race. At the operation the growth was found to involve the uterus, which was also removed. The tumor had probably begun as a fibro-cyst of the uterus which had undergone colloid and partial cystic degeneration. At one point were found a few hairs and a slight osseous formation. The patient had shown no bad symptoms since the operation.

Exsection of the Hip Joint.—Dr. L. H. Sayre presented the remains of the necrosed upper portion of the femur and detritus of the acetabulum removed by exsection in the case of a girl eight years of age, who had for some years suffered from hip disease. The trouble began with pain in the knee. Different forms of apparatus had been applied by physicians in Illinois, Missouri, and Kansas, and with varying degrees of success so far as relief from the symptoms was concerned. There was a phthisical history in the family, and this child was born prematurely between the seventh and eighth months. The operation of exsection was done by Dr. Sayre the present month, and the child was doing well.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of May 19, 1885.

The President, Dr. J. A. McCorkle, in the Chair;
Dr. Z. T. Emery, Secretary.

Cholera Asiatica and Cholera Nostras; their Diagnosis and Treatment, with Special Reference to the Bacillus.—Dr. Arnold Stub read a paper with this title. [See page 32.]

Dr. Chase remarked that the author had stated that raising water to a high temperature would destroy cholera bacilli. Would the cooking of fruit, particularly apples, have the same effect?

Dr. Stub replied that he thought it certainly would, provided that after the apples had been cooked they were not allowed to stand exposed.

Dr. L. Barkan said that, having been deputed by the Austro-Hungarian Government to treat cholera patients, he had had some experience with the disease. He had seen no benefit result from the use of opiates, but had had excellent success with sulphate of quinine. From a theoretical standpoint, he would oppose the use of hot baths, because the increase of temperature might be followed by a marked decrease, in accordance with Traube's theory.

Dr. W. H. Thayer remarked that the paper covered so much ground that he was neither able nor inclined to examine it critically throughout. One or two points, however, in the treatment of cholera appeared to him to be worthy of notice. He could not agree with Dr. Stub in his statement as to the effect of hot baths in the algid state of cholera. It was the experience of many physicians in several epidemics that the use of the hot bath was injurious and fatal to the patient. Dr. Parkes, an East Indian surgeon, who had published a very admirable report on cholera, after five years' experience in India, said patients to whom a warm bath was given invariably came out of it colder than when they went in, and the disease was more rapidly fatal than if the bath had not been given. The speaker was confident that this had been the experience of physicians in other parts of the world, and it had been his experience in the epidemics of 1849 and 1866. A similar statement was made in the report of the Boston Cholera Hospital, in which, in 1849, they treated two hundred and fifty patients. Cold water had not only been more grateful to the patient, but it had had no unpleasant effects. Another point he wished to speak of was the use of opium, which Dr. Stub had advocated. In the speaker's experience, and that of all others who had seen much of cholera, it had been found to be wholly inert after the establishment of the algid stage. It was universally employed in the management of the premonitory diarrhœa, and with great advantage; but it must not hence be inferred that it was applicable to the algid stage. It was possible that its inefficacy was due to the failure of the stomach to absorb it, and that administered hypodermically, as Dr. Stub had recommended, it would have a favorable effect—but that was hypothetical.

Dr. Stub replied that he had not mentioned opium in connection with any stages of the disease except as given hypodermically and in the algid stage, in combination with atropine. Opium internally would be of no use in any other form. With the exception of calomel, he would give no remedy by the mouth. As regarded the question of hot baths, he was not in the position to deny the statements of Dr. Thayer, in former epidemics, but he was of the opinion that, had he not given hot baths to the gentleman connected with the transatlantic steamship company, he would have died. The circulation was very low, and he could feel only the carotids. The radial pulse had ceased beating altogether. The baths instilled new life into him. The pulse became stronger, and he rallied. The speaker had not the least doubt that the experience at Boston, as mentioned by Dr. Thayer, was correct. He was aware and believed that different epidemics of cholera had different features. One epidemic could be managed by certain remedies, while another epidemic required different remedies. So it might be in the instances mentioned. He had had the same experience with yellow fever. In one epidemic a certain course of treatment would prove very efficient, but would fail, perhaps, in the next.

Dr. R. G. Eccles stated that in some late investigations into the literature of disinfectants he had come across an analysis of the results of treatment as compared with non-treatment in a number of cholera outbreaks. Of the patients under medical care, fifty per cent. survived, and, of those left entirely alone, fifty per cent. survived. Among the numerous remedies recommended, the best results had been reported as coming from aqueous solutions of glycerite of tannin, injected as far as possible up into the bowels. One French physician had reported extraordinary success in using this remedy. It was less likely to produce injury than any other. The tannin was decomposed into glucose in the system, so that its products were harmless. It was alleged for this remedy that it destroyed the comma bacilli wherever it came in contact with them, and, by reducing their numbers, necessarily reduced the quantity of poison to which the dangerous symptoms of the disease were due. If treatment had given no better results than non-treatment in the past, and this or any other remedy could save a larger percentage, it would be a blessing to the race. The reader of the paper had said he could see no reason for expecting benefit from inoculation in cholera, since the disease was primarily local. The speaker thought that on *a priori* grounds the experiments were not only justifiable, but commendatory. While the comma bacilli were probably primarily responsible for the disease, all the evil symptoms resulted from absorption into the blood of the ptomaines produced by the micro-organisms. Persons who survived an attack did so because they could resist the paralyzing effects of these toxic agents. Inoculation, perhaps, accustomed the system to these poisons, thus establishing a tolerance like that of the morphine and alcohol habits. Such tolerance might constitute immunity by giving the cells of the body an advantage over their foes, so that the germs could gain no *habitat*, and would fail to multiply. On the question of disinfectants he thought the essayist must have meant that chloride of calcium was almost useless, and not chloride of lime. The latest investigations had shown that good chloride of lime ranked next to corrosive sublimate, both in cheapness and in value as a disinfectant. For

some purposes it was superior to everything else. It not only destroyed the comma bacilli, but quickly and effectually rid us of the most persistent spores known. But it must be good, the tests of which were dryness and solubility in water. If moist, it had too much chloride of calcium; if insoluble, too much lime. Where corrosive sublimate failed, it must take its place. In the dejections of patients, and in sputa, where there was likely to be albumin, mercuric chloride was worse than useless. It coagulated the albumin, forming a protecting sheath, within which the germs were secure from harm. As to the connection between cholera asiatica and cholera nostras, he thought the weight of evidence pointed to their common origin. Continuity in disease would become pretty certain to such physicians as kept their mental eyes open. In scarlet fever it had been observed that exposure sometimes produced symptoms so mild that but few would be bold enough to make a diagnosis. So far as the comma bacillus itself was concerned, the part it played in the disease was not yet certain. A case had been reported of a regiment of soldiers being attacked by cholera in their barracks. After many deaths had occurred they were ordered to tent out a short distance away. They drank the same water, ate the same food, and attended to the same duties, but the mere change of a few perches arrested the outbreak. If their soiled linen, water, hands, or anything else likely to convey micro-organisms had been responsible for the disease, why did it cease on mere change of locality? If Koch was right, while it was advisable for us to disinfect sewers now, it would be a fatal policy to pursue during an epidemic of cholera. We should thus kill the *Bacterium termo*, the natural enemy of the comma bacillus, and give the latter a better chance to multiply.

Dr. Stub wished to mention that tannic acid as an injection had been mentioned by him in his paper as having been very efficient during the last epidemic in France, but he would object to the use of glycerin because it could do no possible good, and might do much harm, for it might deplete the mucous membrane, when our aim should be to add water to the system, and not to deplete the blood still more. He also thought that Dr. Eccles's objection to the bichloride as a disinfectant because it coagulated the albumin might be overcome by the fact that it would kill the bacilli before it coagulated the albumin, and besides, in the speaker's opinion, the bacilli were albuminoid bodies themselves.

(*To be concluded.*)

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of February 12, 1885.

The President, Dr. B. F. Westbrook, in the Chair;
Dr. A. H. P. Leuf, Secretary.

Necrosis of the Femur.—Dr. Justus E. Gregory presented a small sequestrum removed from the inner side of the middle third of the left femur at a point where the femoral artery lies nearest to the shaft of the bone. February 15, 1883, the patient, a man aged forty-six years, consulted him in reference to a carbuncle situated over the left shoulder blade, which was treated by deep incisions. On the 20th of April he complained of a swelling on the front of the left thigh in its upper two thirds, which proved to be an abscess. This was freely laid open and search made for diseased bone or periostitis, neither of which was discovered. After thorough irrigation with bichloride solution (1 to 2,000), large drainage-tubes were introduced and the wound was packed with bichloride gauze. It healed by granulation. In February, 1884, the speaker's attention was called to a sinus which had formed on the anterior surface of the thigh about its middle third and taken a course directly toward the femoral artery. From this sinus there was a slight discharge of pus, and, upon passing a probe, diseased bone was discovered. An operation for its removal was performed by Dr. Wackerhagen on February 5th. Esmarch's bandage having been applied, a large hand probe was introduced into the sinus and followed by incision up to the femoral artery. The opening was enlarged over the course of the vessel, and when the latter was reached it was separated from the bone by retractors, as it actually covered the cloaca. This was enlarged and several small sequestra were removed. The patient recovered, with a perfectly useful limb.

Dr. Kretzschmar desired to know how periostitis could be diagnosticated by simple incision of an abscess.

Dr. Wackerhagen said he had believed at the time that the abscess was due to bone disease, and if he was right it could be better ascertained by the opening of the cavity.

The President remarked that periosteal abscess of the femur was usually so deep that it was hard to find; the abscess in this case was superficial, and so out of the usual course.

Dr. Kretzschmar rejoined that he still failed to see how simply opening the cavity would enable one to make the diagnosis.

Dr. Wackerhagen replied that the abscess was diffuse and had to be opened to let out the pus, and he took advantage of that fact to probe for any of the bone that might be diseased.

Self-mutilation by Amputation of the Genitals.—Dr. H. D. Bliss gave the history of a case he had seen during the summer in the practice of his friend, Dr. J. H. Taylor, of Mount Holly, N. J. A farmer became affected mentally after the death of his wife. He grieved much at the loss of his wife, and, as the neighbors afterward said, acted somewhat queer at times, but continued his work as usual. One morning he was found with his scrotum and penis amputated. The reason, as he explained the next day, was that he had felt impelled to do it, for, as he had been the cause of his wife's death, he thought this would be a relief; so, taking a razor, he had taken the entire external genitals in the left hand, pulled them well out and up, and, with one cut of the razor, severed the entire organs. They were afterward found well connected together. He was not discovered for some time, and it was several hours before the medical attendant arrived. The hæmorrhage, which had not been very considerable, had nearly stopped, except a slight welling up around the urethra, probably from the dorsal arteries of the penis. This was slight, but continued troublesome for several days on account of the difficulty of securing the vessels which lay in close contact with the urethra. It could be stopped with *serre-fines*, but it would begin again every time a catheter was passed. It was finally stopped by applying compound tincture of benzoin. The cut with the razor had exposed the pyramidalis muscle and removed the skin over the pubes, making a wound that could scarcely be covered by the palm of the hand. It was at first intended to dress it with carbolized water, but the nurse allowed it to dry so often that a cloth dipped in carbolized oil was kept over the parts, and the man made a good recovery. The penis being put on the stretch at the time of the cut, the urethra retracted about three fourths of an inch below the surrounding tissue, and there was trouble in keeping it from closing. Catheters of various kinds were tried—silver, rubber, flexible, non-irritant, etc.—but all proved so irritating they had to be discontinued and some other means resorted to. On December 27th Dr. Taylor made a cut an inch and a half down the perinæum, dissected up the skin, and trimmed the tissue so that the integument could be stitched to the urethra. This was done, and all closed with silver wire, and in one week, as the doctor said, "he had a good working urethra."

Among the points of interest in the case were the recovery from the delirium, the speedy recovery of the patient, and the small amount of hæmorrhage from so vascular a structure.

The President related a similar case that had occurred in the Eastern District some years ago, in which the victim's paramour cut off his genitals with a razor, causing fatal hæmorrhage.

A Case of Hysterectomy for Cancer was then related by Dr. W. C. Burke, Jr., of South Norwalk, Conn. [It has already been published.]

Dr. A. H. P. Leuf remarked that he fully coincided with Dr. Burke in considering carcinoma at first local, and thought that thorough eradication of the disease *in loco*, with the extirpation of the first set of lymphatic glands and intermediate lymph-vessels in all cases, as an additional safeguard, would be followed by satisfactory results, if done in time. Many lives, he thought, were sacrificed because of a great lack of fearless and intelligent surgery.

Dr. R. G. Eccles desired to know if any embryologist was present to tell the society about the transition of embryonic cells into pathological cells.

Dr. C. N. D. Jones said that the case just brought before us was another one in favor of the operation.

The President remarked that many of these growths were at first local and benign, and afterward became malignant. This was especially true of the skin, for moles and other benign affections of the integument sometimes, and perhaps in the experience of many present, became malignant. A case had occurred in his experience about one year ago. The patient was a lady who had a "mother's mark" two inches below Poupart's ligament. He did not see it at the beginning, but believed it was a mole, and not a nævus. Subsequently, when she had been sewing with a machine, the irritation due to the friction of her clothing while at work was painful, and caused bleeding. When seen by him, the lesion looked like an excoriation, and it was not raised more above the general surface than was usual in moles. There was no perceptible involvement of the glands. He ordered an ointment. Six months later the patient returned with the sore much worse, painful, bleeding freely, and emitting a very offensive odor. He found a projecting mass about an inch and a half in diameter and fully half an inch high. It had the general appearance of a malignant growth. He removed the whole mass at St. Mary's Hospital. Everything was extirpated down to the cribriform fascia, and the fascia lata scraped for several inches around the original sore. Several affected glands were removed at the same time. A few days later one of the Sisters at the hospital called his attention to a lump over the patient's iliac crest. There seemed to be no connection between this lump and the wound. Two weeks later these nodules developed over the whole body, and a few months after the operation she died in horrible agony. It was hard to account for the malignancy of this case by the accepted views of cancer genesis. Paget's case of cancer at the outer side of the thigh was referred to. The same was true of the female breast. It was notoriously difficult to differentiate between benign and malignant growths. As regarded Dr. Eccles's question, he would say that it had been, and by many was still, maintained that all cancerous growths were developed from the cells of the intermediate layer of the embryo. Cohnheim had asserted that all cancers were congenital. The whole being was abnormal from the onset, and only required an irritation to start the malignant processes. The outer and inner layers of the embryo had between them undeveloped cells, which, by subsequent irritation, became developed into malignant structures. Thus we met with most of these formations in the uterus, gullet, etc. Cohnheim's views were opposed to those of Dr. Burke and others. These latter gentlemen make it local, while the former would have it general.

Dr. Eccles wished to know if Cohnheim's views could not be reconciled with those of the other gentlemen by supposing the irritation to extend after the local disease had existed for a sufficient length of time.

The President replied that Cohnheim supposed that some of the cells in many people had not properly developed, and that it was at such places that cancer began.

Dr. Eccles reiterated the question, whether these cells passed through several stages or at once became cancerous.

The President replied that in embryonic life they became differentiated by a comparatively immediate transition.

Dr. Andrew Otterson had seen a bad case of "cancer" which, after excision, turned out not to be cancer. It was not always easy to make a diagnosis, and more especially a prognosis. Of about twelve patients upon whom he had operated, only two had survived for five years. In one the tumor had been said to be certainly very malignant and in the other doubtful. A former librarian of the Brooklyn Library, fifty years of age, was on a step-ladder, and, while reaching up, fell and struck his breast. It troubled him a good deal. He was under the care of a good surgeon, and was advised to have a resulting lump cut out. Some told him not to have it done. Eventually the speaker cut it out. It came back again in the cicatrix within a year, also involving some of the neighboring parts. No glands appeared to be affected. It was again excised, and again returned in two years and involved the body generally, but more especially the spinal cord and other parts of the nervous system, as shown by post-mortem examination. Another case was that of an old woman in Fulton Market. A boy struck her in the breast with a stone. The resulting nodule remained for years. At last it began to suppurate, and all the neighboring glands were involved. Yet another case was that of a janitor with a nodule of the size of a walnut on the shin from a fall off a step-ladder. It became a suppurating and bleeding sore. The stench was as bad as it could possibly be. The part was very painful. The speaker removed the whole mass with a ligature, and there never had been any return. The man lived for many years, and died of a totally different trouble. He had been sure that this was a case of malignant disease. He believed every practitioner could relate similar cases. As to the indiscriminate removal of all nodules, he thought it impracticable because of the objections on the part of patients.

Dr. Burke said that, as to the justifiability of hysterectomy, he was sure that a large proportion of patients would be saved if surgically treated before it was too late. He had seen an operation two days after his, but the case was so far gone that the patient did not live. There was no peritonitis, but death was due to asthenia. In such advanced cases the operation was not justifiable, but it was if done early and when the disease is local. He thought the operation would become more popular.

Comminuted and Depressed Fracture of the Skull; Trephining; Fungus of the Dura Mater; Recovery.—Dr. Burke then read a paper with this title. [See page 36.]

Dr. R. G. Eccles asked if there had been other psychological effects noticed than those that had been mentioned, for the piece of bone driven into the brain must have entered at about the speech center.

Dr. Burke replied that there had been no such symptoms.

Dr. Eccles: "Has he lost any words?"

Dr. Burke: "No."

Dr. A. Ross Matheson related a case. A piece of frontal and temporal bone about an inch and a half in diameter was driven into the brain by a horse's kick. Fissuring extended

completely across the frontal bone. The upper fragment overlapped the lower fragment. Considerable brain-substance was lost. The case was also seen by Dr. Daniel Ayres, Dr. George K. Smith, and Dr. H. Messenger Ayres. Those parts of the bone that had been driven into the brain were removed. Dr. Smith desired to correct the position of the overlapping fragments, but, Dr. Ayres and the speaker objecting, they remained. There was complete paralysis. Two weeks later a fungus duræ matris developed. It grew as large as the one in Dr. Burke's case. He could not get rid of it by shaving it off a number of times. At last it was sprinkled with sulphate of copper, and a rubber compress was applied. Then it soon healed. At present the patient was well and was an operator in a stock office in Wall Street, New York. The overlapping in the frontal region no longer existed, and in its place could be seen a line of pulsation, half an inch wide, extending all the way across the forehead. He continued a little aphasic for about six weeks after getting up. Now, however, he had no physical or mental symptoms whatever.

Dr. Eccles called attention to the fact that, according to phrenologists, the patient ought to have lost the sense of attention after losing so much cerebral substance from such a locality.

Dr. Matheson stated that the loss of brain substance had amounted to two or three ounces.

Dr. Joseph H. Hunt desired to know if the opening in the skull in Dr. Burke's case had been filled in by new bone.

Dr. Burke replied that it had not, and that at present it was only covered with membrane and skin. During quiescence the skin was sunken in, but when the patient became excited it bulged out.

Dr. Hunt said he had been unusually interested, as he had had a similar case some years ago. The skull was fractured at the vertex and the fragment depressed about an inch. It was removed by Dr. Jarvis S. Wight. The boy was quite well now. There was no fungus duræ matris. The scar looked almost like a fontanelle.

Dr. Leuf remarked that he had seen Dr. Hunt's patient not very long ago and had taken occasion to make some inquiries. He was now a vigorous, healthy, and active young man, engaged in rather hard work. Since the recovery from the injury he had become irascible and rather quick-tempered, qualities diametrically opposed to those he had exhibited previous to the receipt of the injury. The opening was now quite small and triangular in outline. Pressure upon this opening caused the patient to experience a sickish sensation, and, if it was increased, he felt a gradual onset of insensibility. Further than this, he was afraid to have the experiment tried.*

The President remarked that in Dr. Burke's case the motor regions had been involved according to Ferrier and Rolando. Brown-Séquard held that, if one side was injured and its functions were abolished, the other side would assume them in addition to its own. Dr. Burke's case seemed to be a demonstration of the latter view.

Dr. Burke replied that the case had struck him as being so unusual that he had closely observed it from the beginning, but could not say that he had noticed anything in addition to what had already been stated.

Dr. Otterson mentioned a case that he had had in which the brain oozed away for years. Afterward the patient became a conductor on a railway car. His intellect was not in the least impaired. He had never had any unpleasant symptoms of any kind.

* *Note by Dr. Leuf.*—Because of the interest attached to this case, I would mention another fact. Since the meeting of the society the opportunity presented itself to me to sail in a yacht (less than ten days previous to this writing), which was solely managed by Dr. Hunt's former patient. It was done with skill, after a whole morning and early afternoon's hard work of rigging up for the first trip of the season. The sail was such that it required no ordinary amount of skill, care, and ingenuity to get along without mishaps, of which latter we had no experience whatever. This in addition to the above-noted facts connected with the after-effects of loss of brain-substance.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of June 4, 1885.

(*Continued from page 24.*)

Gestation in a Sarcomatous Uterus simulating Extra-uterine Pregnancy. — Dr. Bernardy related the following case: On the 3d of October, 1884, he was requested to visit Mrs. McG., a delicate woman, about thirty years old, whom he found suffering with double pneumonia. At the same time he was told that she was five months pregnant. The abdomen was rather large for that period. On the 5th she complained of a sharp pain in the right inguinal region, which required large doses of morphine before any relief was obtained. He found the right inguinal region filled by an immense growth reaching almost to the lower border of the liver. The uterus, or what appeared to be the uterus, was enlarged and pushed well toward the left side. The right side of the pelvis was filled by a growth. At first he thought he detected fluctuation, but closer examination showed the growth to be hard to the touch. The uterus was immovable, the neck being somewhat absorbed and the os tilted up behind the pubes. To reach it, the finger had to be passed well upward; it was closed and soft. The patient had never had any uterine trouble. The menses had never appeared after her marriage, which occurred one week after a period. Her health remained good for three months after marriage, when, while out walking, she was suddenly seized with a sharp lancinating pain in the right side of the abdomen. The pain was so great that she almost fainted, but finally reached home and went to bed. No physician was called in. The next day there were slight traces of blood on her night-dress. Under absolute rest the pain subsided, and at the end of a week she was about her household duties. The pain in the side returned if she exerted herself. Sexual intercourse was painful and was followed by traces of blood the next day. Believing that the symptoms pointed to either extra-uterine pregnancy or a tumor complicating pregnancy, he asked Dr. Goodell to meet him. By the time the consultation was held, on the 8th, a severe attack of peritonitis had begun. A close examination was therefore impossible. On account of the distended and painful condition of the abdomen, the outline of the growth or uterus could not be traced. It was decided that the symptoms and history pointed to extra-uterine pregnancy, but, whether the uterus contained a tumor or a child, in the present condition of the patient it was impossible to decide. By the 16th the peritonitis was under control, but the lungs were no better. On the 19th he was sent for, the messenger stating that there was a renewal of the peritonitis. He found the patient in active labor, the fœtus descending rapidly. In half an hour labor was completed. He readily detected the large growth filling the upper portion of the right side of the pelvis; the uterus was surrounded by a hard growth. The cervix was hard. From this time the lungs improved, but the patient remained extremely weak and there was a constant dribbling of blood from the vagina. November 3d, the growth was still present and the cervix hard, and he began to think of malignant disease in connection with the tumor. He had applied to the abdomen, night and morning, an ointment of mercurial ointment, belladonna, and iodine, which seemingly had

the effect of causing the absorption of the large growth, but the mass surrounding the uterus remained the same. On the 27th vomiting occurred and was arrested with difficulty; there was a bloody discharge from the vagina and a constant sore feeling over the region of the uterus, which was still toward the left side. The patient was extremely weak; the slightest exertion exhausted her and brought on bleeding from the uterus. December 26th he found her suffering from pleurisy, the left pleural cavity being full of fluid. January 1st abdominal dropsy had set in. A consultation with Dr. Goodell was held, and a positive diagnosis of malignant disease was made. It was thought that death might occur at any moment, and she died suddenly the same evening.

The post-mortem examination, by Dr. E. A. Russell, showed the entire abdominal cavity greatly distended with a dark fluid full of broken-down lymph. The intestines were forced upward. There were slight evidences of beginning peritonitis. A portion of the ileum on the right side presented a black, unhealthy appearance bordering on gangrene. The uterus was increased in size. The outer surface presented an irregular mottled appearance, and large veins covered its surface. At the fundus there appeared a spot, about one inch in diameter, of a bluish tinge. On pressure by the finger the surface readily broke, and underneath was a cavity, of about the size of a large hickory-nut, which did not communicate with the interior of the uterus. The cavity of the uterus was found to be almost obliterated; the tumor seemed to have entirely absorbed the true uterine tissue with the exception of the neck. In the body of the tumor were observed small masses or growths varying in size up to that of an egg. The ovaries were small and seemed to have participated in the general disease. Microscopic examination proved the tumor to be an adeno-sarcoma.

At first the speaker had been convinced that he had a case of extra-uterine pregnancy; but the peculiar hardness of the tumor made him doubtful. Here was a patient that had never had any uterine ailment, who married, became pregnant, at the end of the third month, without any premonition; while quietly walking, was seized with pain of an excruciating nature in the right side, went to bed and remained quiet, and the next day blood flowed from the vagina. She remained comparatively well for two months and a half more, when she was again suddenly seized with pain in the same side, followed by peritonitis. A tumor was found in the affected side; the uterus was enlarged, but not sufficiently so for a five and a half months' pregnancy, the os giving no signs of that softening which should accompany pregnancy. Could we have a group of symptoms more allied to those of extra-uterine pregnancy?

Infant Feeding.—Dr. J. M. Keating said that, at his request, Dr. Charles Potts had instituted a series of experiments which had a decided practical value, and they hoped to present them to the society at an early date. He desired to place on record a statement of the results so far reached, which appeared to be interesting and important. The question often arose, Was it of advantage or not for an infant to be partly nursed and partly bottle-fed? What action had milk upon starch, if any? To answer this the following tests were made: 1. A sample of milk composed of the milk of several women, contained, according to a quantitative estimation by Fehling's method, 6·84 per cent. of sugar. Ten c. cm. of this milk were then taken, ½ gramme of powdered starch was added, and the mixture was allowed to stand at a temperature of 99° F. for thirty minutes, after which 5 c. cm. diluted with 45 c. cm. of distilled water, were tested and showed 8·62 per cent. of sugar. The other 5 c. cm., after standing sixty minutes, gave 9·09 per cent. 2. Another sample, found to contain 7·14 per cent. of sugar, had ½ gramme of powdered starch added as in No. 1. In thirty minutes it gave 9·803 per cent. of sugar in 5 c. cm. The other 5 c. cm., after remaining sixty minutes, gave 8·62 per cent. Possibly part of the sugar deposited was drawn off with the first 5 c. cm. 3. Another sample showed 6·32 per cent. of sugar, and, after the addition of starch as before, gave in the first 5 c. cm. 8·19 per cent., and in the next 5 c. cm. 7·93 per cent. These investigations showed that the women's milk gave an increase of sugar after digesting with starch. 4. A sample of cow's milk was tested and found to contain 3·87 per cent. of sugar. To this was added ½ gramme of starch to 10 c. cm. At the end of thirty minutes 5 c. cm., diluted with 45 c. cm. of distilled water, showed no increase of sugar. 5. A sample of cow's milk gave 4 per cent. of sugar, and was treated as before, but at the end of thirty minutes, and then sixty minutes, it gave the same result. 6. Another sample of cow's milk gave 3·703 per cent. of sugar. It was treated as before, with the same amount of starch. In thirty minutes 5 c. cm. gave the same result; in sixty minutes 5 c. cm. gave the same result. These investigations showed that cow's milk gave no increase of sugar after the addition of starch. Did the acidity of cow's milk prevent the sugar change? Did the sugar change continue in an acid medium? 7. Another sample of human milk—from one woman—yielded 6·25 per cent. of sugar. Starch was added as before. In thirty minutes 5 c. cm. gave 7·14, and in sixty minutes 5 c. cm. gave 7·6 per cent. of sugar. To 10 c. cm. of this milk (containing 6·25 per cent. of sugar) a few drops of dilute hydrochloric acid, enough to faintly acidulate it, were added, and then ½ gramme of starch, and it was allowed to stand as before. In thirty minutes 5 c. cm. gave 6·41 per cent., and in sixty minutes 5 c. cm. gave 7·35 per cent. of sugar. 8. Another sample of woman's milk without starch gave 6·17 per cent., with starch 7·24 per cent. Ten c. cm. of the same, acidulated with hydrochloric acid, diluted, gave in thirty minutes 7·35 per cent. In these tests 10 c. cm. of Fehling's solution were used with 40 c. cm. of distilled water. If future investigations proved the correctness of these statements, we might safely assert that the nursing woman might advantageously supplement her breast milk with some well-prepared digestible form of food containing a small quantity of starch, and also that the amylolytic ferment would remain active in the slightly acid stomach of the infant.

The Surgical Treatment of Infants.—By invitation, Dr. DeForrest Willard read the following paper:

Your committee having invited me to speak to you to-night upon the surgical treatment of infants, I purpose to confine my remarks chiefly to personal experiences in the means of relieving the principal surgical difficulties which are met with during the first two years of life. If the subject shall occasionally lead me to mention older children, it will be because the line between infancy and childhood is not a marked and well-defined one. As you are all active practitioners also, it will be unnecessary for me to dwell upon detail, and I shall only touch upon practical points in treatment.

The surgery of childhood, as compared with that of adult life, is, aside even from congenital defects, sufficiently marked and distinctive to entitle it to separate consideration. First of all must the children's surgeon acquaint himself with the anatomy of the child. This is rarely done, as the ordinary adult dissections during a college course give little idea of the size and position of the individual elements as seen in the infant. In consequence of ignorance upon this practical point many grievous failures have occurred. After unusually large opportunities for the study of both normal and abnormal tissues in the diminutive frame, I am still frequently surprised to note the exceeding smallness of different organs and canals.

Another essential element in the surgeon is tact in the management of the little ones, especially when dealing with those

between the ages of two and ten. In hospital cases but little history is attainable, and much depends upon quick perception. Naturally fearful of pain, the patient's mind must be diverted and engaged, or great difficulties in diagnosis will often occur from the fright and struggling. The operator not in sympathy with children can never secure their confidence. Much will often be gained by quiet observation. It is not a month since my opinion, which at the first few moments of the consultation had been favorable to tracheotomy, was changed by five minutes' close watching, and the result proved the correctness of the procedure. To the person, however, who will carefully study individuality as well as disease, no department of medicine offers so pleasant a return for his labors. My personal experience with children has perhaps made me more hopeful in regard to the power of such individuals to endure pain, shock, and disease, than would be indicated by the expressions of other authors, but to me there is no domain of surgery so attractive and gratifying as the treatment of children below the age of puberty. Their natural condition is that of hopefulness, and, as soon as the depressing influence of shock, pain, or fear is removed, the normal resiliency of mind and body asserts itself with such rapidity that the results are often surprising.

Again, a child has only inherited taints of constitution to contend against; his viscera are ordinarily in a healthy condition; an adult has not only hereditary but all the acquired vices occasioned by misuse or abuse of any organ or sets of organs, a circumstance which often turns the scale in the struggle between life and death. Take, for example, the single instance of the outraging of tissues by either the moderate or the excessive use of alcohol, and every surgeon will testify that even slight wounds may, in such an individual, quickly develop a fatal attack of *mania a potu*. Tetanus is not more frequent in infants than in adults, notwithstanding the tendency of the former to nerve excitability.

In regard to anæsthetics, my experience is that great benefit is obtained by the use of ether when pain can thereby be prevented. In the first weeks of existence I admit that a feeble vitality would contra-indicate its use, although I have successfully administered it to an infant three days old. After the first or second month, I see no reason why we should needlessly inflict pain upon an infant simply because we can control it by brute force. In the examination of fractures great suffering is often inflicted by careless and frequent manipulation, and, unless the diagnosis is easy and positive, unconsciousness should be produced. No case of bone injury should ever be passed by undiagnosticated when ether will solve the question. In the opening of abscesses the "primary quieting influence" of ether is so readily obtained that it should be brought into use whenever practicable, as keenness of pain can thereby be avoided.

Fear plays an important part, and may depress the child's system even more than pain; hence great caution should be observed that all knowledge of any operative procedure should be guarded against. When the day for action arrives, let the surgeon quietly and gently state to the little one, if it has arrived at years of reason, just what it is proposed to do, at the same time assuring him that no pain will be experienced, and, if such words are followed by firm, speedy, and judicious management, much agitation and fear will be avoided. All preparations should be made out of sight and hearing of the patient, and instruments need never be seen by him, except when a strong impression is intended to be made upon the mind of a masturbating boy requiring circumcision, in which case ether may also be omitted.

One word in regard to the method of anæsthetization. It is but natural that a child should be distrustful of any attempt to deprive him of consciousness, a fear which is greatly increased by the injudicious and greatly-to-be-condemned habit of many parents, who systematically threaten their offspring with the expression, "The doctor will come and cut your head off." A few kind words will often quiet the agitation, and simple directions as to the method of breathing will save many minutes of struggling resistance. With very young children, the first smell of ether may be masked by permitting them to see cologne poured upon the towel, after which ether may be quietly added, and they will feel that it is a perfume that they are breathing. This device has frequently served me a good purpose. I always allow a good admixture of fresh air for the first moment, but, when the child actually begins to cry, then quick action answers best. The towel should now be well saturated and held firmly over nose and mouth until two or three strong screams and inhalations yield a full primary impression, which can be gradually followed up to complete anæsthesia with safety.

Should any symptoms of ether narcosis occur, it is so easy to depress the head of a child, or to perform artificial respiration by acting upon the ribs, that serious accidents are infrequent. Subsequent vomiting is very common but is not persistent, and is easily quieted by a small hypodermic of morphine, a procedure which ordinarily brings quiet sleep to the patient. If the child is feeble, I always allow milk up to within two or three hours of the operation, and then administer wine or whisky in water immediately before giving the anæsthetic. Milk with lime-water and whisky is usually retained within ten minutes after the first vomiting on rousing. In tedious excisions, not only should preliminary precautions be taken to secure against prostration by shock, but hot-water bags should be ready for use, which, with hypodermics of brandy, may succeed in tiding over a temporary depression which would otherwise end in death. When the loss of blood has been great, especially in acute surgery, important assistance may be gained by transfusion, either of blood or of a warm saline solution.

Under the head of arrest of hæmorrhage I would strongly advocate the use of animal ligatures, since the pain often incident upon the removal of threads greatly disturbs the needed quietude of wound and mind.

Thorough asepsis and antisepsis are especially valuable since we not only secure the admirable results that are attainable by their use, but are also enabled to disturb the child with far less frequency. I am now treating a girl with a railroad crush of the leg which would thoroughly have justified amputation, yet which, under corrosive-sublimate dressings, has been touched but six times in as many weeks, even though extensive sloughing has occurred. Save upon one occasion, at the height of the process of tissue-death, the applications have been taken away perfectly sweet, and the child has the promise of a reasonably good limb. In my *septic* days I certainly was never able to carry a patient through such a process and keep the temperature, as has been done in this case, below 99·5° F. all the time, and usually but slightly above 98°. With infrequent dressings, the irritation of the child is but slight, and, if pain is also absent, contentment is the rule, under proper nursing.

I can not too strongly emphasize the importance of this latter condition. A kind, quiet, gentle nurse is one of the most valuable assistants in the real progress of the case, especially during the first week following an operation. Such care can not be delegated to untrained and careless people, hence it is absolutely necessary that children should be in separate hospitals, or in separate wards, under the best of care-takers. Even in private practice the mother is rarely the best nurse for a child past two or three years of age, and a skilled attendant answers best. In hospital practice I have often been surprised

to see how contented and patient the majority of children of even three years of age will become if the mother maintains a judicious absence and the nurse is efficient and kind.

Another point which I wish most emphatically to emphasize to-night is the fact that congenital defects are most inexcusably and persistently neglected by even good practitioners, under the mistaken opinion either that nothing can be done, or that a later period will be early enough. The consequence is that many unfortunates become helpless and hopeless cripples by their physicians' advice, since, passing out of his sight and mind, the neglect engendered by his direction, "wait," is fostered by parents, ever ready to postpone a dreaded day.

Turning to some of the special surgical diseases of infants, I would say that it is my intention to simply touch upon a few points of treatment without regard to definite arrangement or order, since to consider almost any one of the conditions in full would require an entire evening's discussion.

In a new-born child the first most probable trouble requiring surgical relief will be *imperforate anus* or *rectum*. Such a condition is not improbable when we remember that the intestine is formed as a closed tube. If the malformation is simply one of occlusion of the anus by a membrane, it would seem to be the easiest of procedures for any practitioner to make an opening, yet I have seen children permitted to die with the entire ischio-rectal fossa and perinæum bulging with retained fæces, when a simple puncture through a membrane closing an otherwise normal anus would have given immediate relief. This timidity may perhaps be explained by the fact that occluded anus and imperforate anus are confounded with imperforate rectum and the case is given up as hopeless. In imperforate anus the operation is still a simple one, since a crucial incision, together with stitching of the mucous membrane to the skin and subsequent dilatation with the finger or probe, is all that is required.

When the anus is normal and patulous, but the rectum is occluded by a membrane, or is actually absent, a much more serious condition presents itself, the difficulty increasing in proportion to the extent of the deficiency. Should no meconium be passed within the first twenty-four hours, a careful search should be instituted. The little finger or a catheter passed into the anus will detect the obstruction, or, if the anus is absent, the vagina, if present, may be explored for abnormal fistulæ. As soon as the presence of fæces can be discovered in the fossa, a careful dissection should be made, keeping well backward, so as to avoid the vagina, or the urethra and bladder. A catheter should always mark the position of the urethra. There is but little danger, even in deep incisions, if the region of the coccyx and sacrum is followed. The gut found, it should be drawn down as far as possible and secured, a channel being maintained through the lower rectal region, if necessary, by the finger or by bougies, the latter of which should not, however, be retained constantly in position. There is much less danger from subsequent hæmorrhage if the external incision is free, and no fear need be entertained about the ultimate retention of fæces, as, if the child escapes peritonitis and other inflammations, good control of the bowel is always secured; in fact, the chief subsequent danger lies in the formation of stricture. When the length of the bowel will not permit it to reach to the site of the anus, the new opening may be made nearer to the sacrum. Should no trace of the rectum be found within two inches of the anus, it is unsafe to further explore a region where the peritonæum would be liable to injury; either left inguinal or left lumbar colotomy should be performed. The right groin is to be selected if there are evidences of absence of the sigmoid flexure. The left inguinal position gives a better subsequent opportunity of passing a bougie downward into the rectum and thus establishing a proper anus. If the colon is full, it will not be difficult to find. In cases of doubt, its distension by air or water through a hypodermic needle would determine its termination. Abnormal openings into the vagina, bladder, or urethra rarely require early operation, but, in non-retention of fæces at a later age, Rizzoli's plan of procedure is a good one.

Later in childhood, the surgeon is often compelled to treat another condition of the rectum, namely, prolapse. This, if excessive and non-yielding to replacement, astringent applications, hot water bathings, and general constitutional measures, must be cured by the production of linear eschars by nitric acid.

The genito-urinary organs may also require attention immediately after birth. A simple occluded urethra is easily relieved by the careful introduction of a sound or catheter. *Epispadias*, *hypospadias*, and *exstrophy of the bladder* should not be allowed to go on to adult life without relief. As soon as the child has passed its dentition period, a plastic operation should be attempted for relief, since the mental and moral effect of such a deformity has often a marked influence upon the lives of the unfortunates. *Adhesion of the vulva or nymphæ* should not be overlooked, since not only does the nervous system suffer, but the parts may be improperly developed. Separation can almost always be accomplished by the finger or by a probe. An absolutely *imperforate hymen* should never be allowed to exist if discovered, since, if permitted to impede the menstrual flow, at a later period, serious and even fatal results may follow its division, if the uterus and Fallopian tubes have become dilated by the imprisoned secretion. *Imperforate vagina* should receive at least careful diagnostic attention to detect the presence of a uterus, and, if this is not absent, fuller development will be secured if the passage can be opened during the first few years of life. With a catheter in the urethra and a finger in the rectum, a careful operator can explore safely. I have met with several cases in which the *penis* was preternaturally *short* and ill formed, the body of the organ, during flaccidity, being almost entirely concealed in the fatty tissues of the pubes. In such instances I have removed the prepuce during the first three months of life, and have cut away all restricting bands of skin and connective tissue, sometimes even drawing beneath the penis an extra flap of skin when the corpus spongiosum has been short and dwarfed. By such means the fullest amount of growth is encouraged.

Adherent and *contracted prepuce*, or *phimosis*, has been the subject of much discussion in regard to its causal influence upon certain nervous manifestations. My views upon this subject have been already published,* and, after two years of additional experience, during which time I have been brought daily in contact with this class of cases, I can reiterate what I then stated, namely, that, while more or less adhesion is an almost constant and normal condition, yet, when urinary, choreic, paretic, or any other nervous symptoms develop, a careful investigation should never be omitted, since a direct relation will in a certain number of cases be clearly evidenced, and removal of the cause will speedily cure the manifestation. The fact that even circumcision does not relieve the symptoms is undoubtedly true in many instances, and I have never maintained that preputial adhesion and narrowing was anything more than one of several factors which should be carefully scrutinized. I have only urged that its influence should not be overlooked, and, when so simple an operation as stripping the prepuce from the glans by the thumbs, or possibly by the use of a probe, is all-sufficient, there can certainly be no argument against removing this one factor. My opinion in regard to the feasibility of

* "Philadelphia Medical Times," June 30, 1883.

drawing back the prepuce in young children, even when the opening seems scarcely pin-hole in diameter, has been greatly strengthened, and circumcision is only necessary when the simpler method described fails to secure a prepuce freely movable over a normal glans. Dilatation even is but rarely required, a few minutes of continuous pressure soon revealing the mucous layer, adherent perhaps just about the meatus, which, when loosened, permits the head to pass through the opening, and the corona is freed with the thumbs. Should temporary paraphimosis occur, two probes or a hair-pin slipped beneath the constriction will easily permit replacement.

(*To be concluded.*)

Miscellany.

The American Medical Association and the International Medical Congress.—"The meeting of the American Medical Association, held at New Orleans during the past month," says the "Kansas City Medical Record," in its June issue, "did not prove to be as much of a success as was anticipated. We presume this may be accounted for on the ground of the location, the country in the vicinity of New Orleans being sparsely occupied by physicians, and the territory well occupied by the profession being at a great distance, rendering it a tedious journey at a great sacrifice of time. Hence the attendance from our large Eastern and Northern cities was very light.

"There were about five hundred physicians present, mostly from the South and West. The papers read, both in general session and sections, were quite practical as a rule, and full of interest, and received a pretty thorough discussion.

"Many of the leading representative men who usually attend the meetings being absent detracted from the general interest, and prevented the meeting reaching the average standard of American Medical Association meetings. . . .

"The second day of the meeting was ushered in by a somewhat verbose discussion regarding the action of the committee relative to the International Medical Congress. From our best information regarding the gentlemen who were instrumental in initiating this uncalled-for wind-storm, we fancy the trouble originated from disappointment. They are sore-heads of the 'rule or ruin' type. Some of these men have for years endeavored to supply the wind-power for the American Medical Association meetings.

"The International Medical Congress requires a more reliable power—a steadier power; hence these dress-parade sort of fellows were, of necessity to the welfare of the Congress, relegated to the rear.

"In order to conceal the true character of the charges, they hid behind the new-code prejudices charging that new-code men were put on the committees. However objectionable the new-code men may be, we hope they are governed by purer principles than men whom we know to be ostensibly sticklers for old-code theories, but are practically no-code practitioners, except such as will give them personal aggrandizement.

"We have carefully looked over the 'rules and preliminary organization,' and can see no reason to find fault with the action of the committee. We feel entirely satisfied that they have acted in the best interest of the American profession in general. Nearly all the States, the District of Columbia, and Canada have been represented by the appointment of prominent and distinguished physicians on the committees and sections. New York, having the largest number of widely known men, is justly entitled to a larger number of representatives, and therefore has 68 appointments; Pennsylvania, which might be expected to come next, has 48; Massachusetts, 32; Illinois, 18; Ohio, 15; District of Columbia, 18; Missouri, 8. A few States are left out, which can be the only tangible objection to the appointments.

"It must not be forgotten that the States so largely represented are those in which most of the medical teachers and authors reside, without whom, be they new- or old-code men, the American profession could not be represented in its best light, which, above everything of a technical nature, should be sought after."

The Use of Cocaine in Nervous Affections.—At the recent meeting of the American Neurological Association, Dr. J. K. Bauduy, of St. Louis, read a paper in which he recounted his experience with the use of cocaine in the treatment of certain forms of psychical disturbance. We expect to publish Dr. Bauduy's paper shortly. In the mean time, we would call attention to a letter which has been shown us, written by Dr. L. Bremer, of St. Louis, from which we make the following extracts: "Dr. Bauduy, of this city, has been using the cocaine in cases of melancholia with the happiest results. During a recent visit at St. Vincent's Hospital I was, by the kindness of the doctor, afforded an opportunity of witnessing the rapid and wonderful effect which the hypodermic injection of one grain of the drug produced in the affection named. W. H., aged seventeen, who was under my treatment before his admission to the hospital, for hebephrenia, and whose mental state I am thoroughly familiar with, was, on our visit, found in a condition of great depression. Although he knew me well, he refused to speak to or recognize me. The expression of his face was that of utter dejection, despair, and disgust. All efforts to elicit an answer to my questions failed; he remained wrapped up in a sullen silence. The injection of one grain of cocaine changed the scene as by magic. Four minutes after the introduction of the drug the patient began to talk; the spell was broken, and he conversed freely and intelligently on the nature of his trouble. The almost mathematical precision of the effect of the remedy could only be compared to that of morphine in certain nervous affections.

"The second case in which the cocaine was tried in my presence, and yielded a like brilliant result, was that of a young man suffering from a severe form of melancholia combined with a refusal to take nourishment. Five minutes after the administration of the drug he became quiet and partook readily of the nourishment offered to him. This patient would never eat except when under the influence of the drug; it was employed for the first time when he was approaching inanition, to avert which the feeding-tube was thought of as a last resort. . . . To my knowledge, Dr. Bauduy has been the first to try cocaine in melancholia."

Dr. Bauduy seems to have been the first also to suggest the use of cocaine for the morning sickness of pregnancy. An interesting account of Dr. Schenck's experience with the remedy for that distressing condition will be found in the report of the proceedings of the St. Louis Medico-Chirurgical Society, published in the "St. Louis Courier of Medicine" for May, where it is expressly stated that the cocaine was used at the suggestion of Dr. Bauduy.

The New York Polyclinic.—Dr. M. Allen Starr has been elected professor of diseases of the mind and nervous system in the New York Polyclinic.

The "International Journal of the Medical Sciences."—Beginning with the issue for January, 1886, according to the "British Medical Journal," this will be the title of the "American Journal of the Medical Sciences," Dr. Hays continuing as the American editor, and Mr. Malcolm Morris being the European editor.

The Health of the State of New York.—It appears, by the "Monthly Bulletin" issued by the State Board of Health for the month of May, that the total reported mortality was 6,542, the percentage of infant mortality being 32·23. In each thousand deaths there were 154·70 from zymotic diseases, including 26·83 from measles, 18·70 from scarlet fever, and 48·91 from croup and diphtheria.

The Health of Michigan.—From a statement issued by the secretary of the State Board of Health, Dr. Henry B. Baker, we find that, during the month of June, diphtheria was reported from forty-one places, scarlet fever from twenty-seven, measles from sixteen, and small-pox from two.

The Missouri State Board of Health was lately reorganized by the choice of Mr. William Gentry as president, Dr. George Homan as secretary, and Mr. J. B. Prather as treasurer.

THERAPEUTICAL NOTES.

A New Species of Agaric.—Grossi, says the "Gazzetta degli ospitali" (quoting from "Rif. med."), has recently made a study of a gigantic species of agaric, the *Polyporus senex*, found on the coast of Chile, the absorbent properties of which are remarkable. Although it is insoluble in ether, in chloroform, and in alcohol, it effervesces in the presence of bicarbonate of sodium, becomes smooth and unctuous, breaks up, and dissolves. Grossi has made use of it as a styptic, and regards it as a specific in cases of hæmorrhage from wounded arteries that are too small to tie, and too large to be controlled by other styptics; also in the hæmorrhagic diathesis. He has employed it for night-sweats also, after the following formula:

Polyporus senex	3¼ grains;
Bicarbonate of sodium	15 "
Distilled water	3 ounces;
Gum arabic	75 grains.

A tablespoonful to be taken at night.

A New Basis for Ointments and Suppositories.—In the same publications it is stated that the seeds of the *Hopea splendida* and the *Hopea aspera*, if not those of some other species, furnish a fatty matter, known in the Islands of Sunda as *myniak-tangkawank* or *myniak-sangkawank*, which is used in the industrial arts, and seems likely to answer in the preparation of ointments and suppositories.

The Treatment of Goitre with Iodoform Injections.—Thiroux (Thèse de Paris, 1884; "Rev. méd.") records several cases in which interstitial injections of iodoform were followed by considerable improvement and even cure. At the military hospital at Bordeaux these injections have been found to give so much pain, due probably to the ether in which the iodoform was dissolved, that their use has been given up.

Parthenine in the Treatment of Facial Neuralgia.—Tovar has experimented with this alkaloid in cases of facial neuralgia ("Gazz. med. Ital.-Lombard."). Giving a tenth of a grain every hour for four hours, and then decreasing the size and frequency of the dose, he cured rather a severe case in a week. Parthenine is obtained from *Parthenium hysterophorus*, an herb growing in Jamaica, where it is much used for cutaneous affections.

Anisic Acid as an Antipyretic.—This substance (*Ibid.*), obtained by the oxidation of oil of anise, takes the form of colorless prismatic crystals soluble in alcohol and in ether. It has antiseptic properties, also an antipyretic action analogous to that of salicylic acid. It should be used with caution, as large doses injected into the veins of various animals have caused epileptoid convulsions.

A Ready Method of stopping Hiccough.—A Brazilian physician, Dr. Ramos ("Bull. gén. de thérap."), states that refrigeration of the lobe of the ear will stop hiccough, whatever its cause may be. Very slight refrigeration will answer—the application of cold water or even of saliva being sufficient.

The Fruit of the Calabash Tree as a Purgative.—According to Peckolt ("Nouveaux remèdes"), both the pulp and the expressed juice of this South American tree, the *Crescentia cujete* [Linnæus], have long been used as laxatives in Brazil. The alcoholic extract, in doses of a grain and a half, is a laxative, and acts as a drastic in doses of seven or eight grains. The fresh pulp is also employed as an application in cases of erysipelas. It is boiled with water until it forms a black paste, then vinegar is added, and the mixture is boiled again. It is applied spread on linen.

Hydrofluorate of Quinine.—According to Weddel (*Ibid.*), this salt is soluble in water and in alcohol. He has used it in the treatment of hepatic engorgements of malarial origin, in which, he thinks, fluorine and the fluorides have a beneficial action. He has observed the same in rickets and other nutritive diseases of the bones.

Paraldehyde as a Hypnotic.—At a recent meeting of the North of Ireland Branch of the British Medical Association ("Brit. Med. Jour."), Mr. Hodgson, of Brighton, gave his experience with this drug in cases of insomnia unaccompanied by pain, especially in mania, hypochondriasis, delirium tremens, and [so the account states] migraine. As compared with chloral, it had the advantage of not being a cardiac depressant. For gout, both acute and chronic, he strongly recommended it, finding that sleep was obtained, while the solid constituents of the urine were increased rather than diminished. When either the throat or the stomach was inflamed, it was unsuitable, owing to its pungeney, and this quality rendered free dilution always necessary. As an anodyne, he considered it weak, but he had found that it heightened the effect of morphine.

Anagyrine.—This is the name given to an alkaloid extracted by Hardy and Gallois from *Anagyris fœtida* and *A. indica*. At a recent meeting of the *Société de biologie* ("Gaz. hebdom. de méd. et de chir."), M. Hardy reported that small doses had been found to act as a tonic, but that large doses, given to small animals, produced death by arresting the respiration.

Deelina Oil in the Treatment of Skin Diseases.—Dr. John Roberts, of Chester, England ("Practitioner"), gives brief notes of a number of cases of skin disease, chiefly of an eczematous character, in which he has used "oleum deelinæ" as a topical application. He considers it superior to all other fatty substances for the purpose. He never uses it during the acute stage. Before it is applied the parts are bathed with warm bran-water or oatmeal-water, and then carefully and gently dried. All that is said of the nature of the oil is that it is "another member of the hydro-carbon family," and that it is "manufactured on the banks of the Dee, by the Dee Oil Company, by a process of refining," etc. We find nothing in the article to indicate whether it is a fish-oil, a petroleum product, or of vegetable origin. It is said that it is clean and inodorous, does not become rancid, and leaves little or no greasiness after its application.

Iodoform in the Treatment of Syphilis.—Dr. H. Macnaughton Jones (*Ibid.*) states his experience of the value of iodoform administered internally in certain cases of syphilis in which the iodides appeared to have little effect. He does not generally give it in larger doses than a grain or a grain and a half, three times a day. He continues its use, unless it is contra-indicated by some sense of fullness in the head or headache. Especially when used in conjunction with the external application of iodide of starch, he has seen it prove of striking benefit in cases of ecthymatous ulceration. Like iodide of potassium, it is not borne in any quantity by some persons, while there are others who can safely persevere with it for a considerable time.

An Anæsthetic Mixture of Dimethylacetal and Chloroform, two volumes of the former to one of the latter, has been used at the Strassburg surgical clinic in a hundred and fifty cases. Fischer ("Dtsch. Ztschr. f. Chir."; "Ctrlbl. f. Chir.") says that its advantages are that psychical excitement and muscular agitation do not occur, but the patients pass gradually into a quiet sleep; that vomiting, and efforts at vomiting, are not observed during the anæsthesia, and occurred after consciousness was regained in only four cases (those of very anæmic patients who had been allowed to drink a good deal after the operation); and that the disappearance of the anæsthesia is very rapid, and leaves the patient feeling comfortable, without any headache. The mixture is recommended: 1. When gastric catarrh and vomiting are especially to be avoided. 2. For laparotomy. 3. In cases of heart disease. 4. In nephritis. 5. In diseases of the central nervous system, particularly infantile paralysis and epilepsy. 6. In cases in which untoward symptoms come on during chloroform anæsthesia and the operation can be completed only with the aid of an anæsthetic. The drawbacks are the slowness with which anæsthesia is induced in robust, muscular individuals, and the high price of dimethylacetal.

The External Use of Chloral for Night-Sweats.—Nicolai ("Wratsch"; "St. Petersb. med. Woch.") remarks that the usual remedies for night-sweats have the disadvantage that the system soon becomes accustomed to their action, and that, consequently, the dose has to be so increased that unpleasant collateral effects are produced. The external use of chloral, he says, is free from this objection. He uses a mixture of two drachms of chloral and two beerglassfuls of equal parts of brandy and water. With this mixture the patient is bathed at bedtime. If this is not enough, a clean night-shirt is put on which has been soaked in the solution and then dried. This treatment is said to be particularly successful with children when the trouble is not due to phthisis.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M.D., NEW YORK.

(*Continued from page 32.*)

THE CARE OF A BATTERY.

THE best battery is liable to get out of order. It is an easy matter, as a rule, to correct the trouble if the construction of the apparatus is thoroughly understood. The following hints may aid the reader in obtaining a satisfactory current with a minimum expense:

1. *Keep your battery clean and bright in all its parts.* Close the case when the battery is not in use, and thus keep out dust, grease, and moisture. Emery-paper is useful to keep the metal connections free from rust. Remember that dirt, grease, or rust will often arrest the action of any battery.

2. When the battery fails to act properly, examine the cells first and see if *the fluid requires renewal.* The "red-acid fluid" is easily made by adding one part of commercial sulphuric acid to ten parts of cold water; when cooled, one part of finely pulverized bichromate of potassium should be added and mixed well. This is the fluid commonly employed in portable batteries with cells of the Grenet pattern.

3. If the fluid is found to be fresh, and if the zinc and carbon elements are in good order and the zinc well amalgamated, *examine carefully all the screws and other connections attached to the elements* and see if they have become oxidized. Sometimes they become rusted or so covered with accumulated dirt as to render the passage of the current impossible. Occasionally the carbons may be disconnected and baked in an oven to render a Grenet cell more active. Soaking the elements (*in situ*) in hot water which does not reach the connections will generally suffice to cleanse them.

4. If the *cell has become polarized* when in action (by bubbles of hydrogen which accumulate upon the carbon and of oxygen upon the zinc element), lifting the zinc out of the fluid and replacing it immediately will suffice to overcome this trouble if the cells are of the Grenet pattern. These bubbles of hydrogen and oxygen set up a counter-current in the cell which will weaken and may even neutralize the original current.

5. *Examine the interrupter*, the *buttons of the current-selector*, and *the commutator* for rust or dirt, and clean each thoroughly when the trouble appears not to be due to the elements or their immediate connections.

6. If a *drip-cup is furnished* with a faradaic or galvanic battery, be careful to place the zinc element in it when the battery is not in use.

7. In portable galvanic batteries, be sure to *place the rubber-covered diaphragm over the cells* before closing the case and to screw it down tightly. This prevents the fumes rising and oxidizing the connections of the elements when not in use. This does not apply to a red-acid battery when not being transported.

8. Be sure that the *rheophores are perfect* before they are used upon a patient. The wire used in their manufacture is liable to become broken or oxidized by use. This is especially true of the flexible, cotton-covered cords generally furnished with batteries. The electrodes may be tested by employing a galvanometer, if an imperfection is suspected and can not be found.

9. The *wires* that run from the cups to the buttons of the current-selector or the commutator may be seen on the bottom side of the key-board of a battery. They can be examined for imperfections when the other parts of the apparatus appear to be perfect.

10. *Do not short-circuit a battery.* By this we mean, do not allow a battery to run down, or, more technically, "polarize," by the poles being brought into contact without an interposed body (such as animal tissue) for any length of time. For example, galvanic cells which have a low internal resistance (as a Grenet cell) become polarized in a few hours when the poles are connected by a short wire which affords little if any resistance to the current.

11. *Keep your electrodes clean.* It is well to cover them with fresh canton-flannel for every patient. This is an act of precaution which will impress people with your regard for their feelings and for their safety from contact with infectious matter. Sponges are too expensive to be renewed so often. Absorbent cotton may often be placed between the electrode and its covering with advantage.

PART II.

THE PRINCIPLES OF ELECTRO-DIAGNOSIS.*

The various electric tests that are employed as aids in the diagnosis of nervous affections are too complex to be fully described and explained without entering somewhat into the domain of physics and physiology. Erb† has lately written an excellent work upon the subject, and most of the later treatises upon physiology will afford you general information respecting the reactions of healthy muscle to the faradaic and galvanic currents. The few practical hints which are given here are offered with an apology for their incompleteness, although it is hoped that they will assist you in your studies in this field.

Having first moistened the electrodes and connected them with the battery in action, it is customary to hold them both in one hand (close together, but not in contact), and apply them to the ball of the thumb of the opposite hand or the cheek to see if the current is passing properly. If the current to be employed is a *very weak one*, touch the electrodes to the tip of the tongue before it is used upon the patient.

Next, sponge the part of the patient's body to be tested with a *weak solution of table-salt in warm water*, in order to

* Portions of this lecture have already been published.

† "Handbook of Electro-Therapeutics," New York, 1883.

render the skin a good conductor of the electric currents. If the wire-brush is to be used, this step is omitted.

The "*polar method*" is the one commonly used. Apply one electrode of large size, either over the breast-bone of the patient (at about its center) or over the back of the neck. The breast-bone is the preferable point on account of the absence of muscles in the median line.* The other electrode (of small size) is placed over some special nerve-trunk or the muscle to be tested; in case muscle is to be tested, the electrode is placed usually at the point where the motor nerve enters its substance—the so-called "motor-point" of the muscle. In this way the action of the two poles can be readily distinguished.

In my work, "The Applied Anatomy of the Nervous System," I have reproduced von Ziemssen's cuts, illustrating the situation of the motor-points of the various muscles. In case the interrupted or faradaic current is to be employed, the "polar method" need not be strictly adhered to, as it is decidedly more painful than when the electrodes are less widely separated.

Use both the *continuous or galvanic current* and the *interrupted or faradaic current* in testing muscular reactions. The former is of the greatest value in diagnosis.

In *studying the muscular reactions to the different currents* employed, remember (1) that the negative pole is called the cathode (C),† and the positive pole the anode (A); (2) that muscular contractions occur both when the current is altered in strength and when the circuit is closed or opened; (3) that the faradaic current produces an apparently continuous muscular contraction, because its interruptions are so very rapid; (4) that very weak currents do not produce contractions; (5) that alterations in the strength of the current cause proportionate variations in the contractions; (6) that the contractions are short, sharp, and sudden in health; (7) that the effects of applying the electrode over the substance of the muscle and over its motor-point are identical in health, but not in some diseased conditions; (8) that the galvanic current will not usually produce muscular contractions while it is constant, but only when its strength is modified or when the circuit is closed or broken; (9) that the direction of the current can be changed, without altering the position of the electrodes, by a simple apparatus that changes the cathode into the anode, and *vice versa* (the *commutator*).

The current passes always from the anode to the cathode. Hence, when the positive pole is placed on the breast or neck, and the other on the muscle to be tested, we have a *descending current*. An *ascending current* exists if the anode is on the same distant or neutral point.

An "automatic interrupter" on an "interrupting electrode" is necessary in employing the galvanic current in testing muscular reactions.

The *descending current*, when closed and again broken, can thus give us:

1. The cathodal closure contraction:
   C. C. C. or Ka S. Z. of the Germans.
2. The cathodal opening contraction:
   C. O. C. or Ka O. Z. of the Germans.

The *ascending current*, when closed and again broken, can give us:

1. The anodal closure contraction:
   A. C. C. or An S. Z. of the Germans.
2. The anodal opening contraction:
   A. O. C. or An O. Z. of the Germans.

These four forms of contraction require currents of different strengths to produce them. They are, therefore, induced by *gradually increasing the number of cells* employed. The following order is the one commonly observed in healthy muscle:

1. . . . . C. C. C. = Ka S. Z.
2. . . . . A. C. C. = An S. Z.
3. . . . . A. O. C. = An O. Z.
4. . . . . C. O. C. = Ka O. Z.

It will be observed that the *cathodal contractions* appear first and last in health, while the *anodal contractions* follow each other; also, that the *closure contractions* precede the *opening contractions* of both the cathode and anode. When a nerve-trunk is stimulated by electric currents the formula of the normal muscular contractions is altered. This will be spoken of hereafter.

As the strength of the current is gradually increased, the contractions which have successively appeared *become intensified proportionately* (as is shown below), and *new reactions* are added:

First stage (*moderate current*), C. C. C.
Second stage (*stronger current*), C.′ C.′ C.′ and A. C. C.
Third stage (*still stronger current*), C.″ C.″ C.″ and A.′ C.′ C.′ and A. O. C.
Fourth stage (*very strong current*), C.‴ C.‴ C.‴ and A.″ C.″ C.″ and A.′ O.′ C.′ and C. O. C.
C.‴ C.‴ C.‴ is called "*cathodal tetanus*," because the contraction is very violent. Sometimes the anodal contractions both occur with the same intensity of current, thus merging the second and third stages into one. Again, A. O. C. may in some cases appear before A. C. C.

Disease of the nerve-centers or of the nerves themselves may cause modifications of the normal formula of muscular contractions. This constitutes the key-note to the value of electric currents in diagnosis. Mechanical devices may be employed to trace the muscular contractions, as the sphygmograph does the pulse. (Fig. 32.)

If the destructive process is within the brain or spinal cord, and *situated above the* "*trophic centers*" of the nerves supplying the paralyzed muscles, the electrical reactions of the paralyzed muscles will be normal in respect to the sequence and character of the muscular contractions. Sometimes, however, a *much stronger current* (galvanic or faradaic) is required to produce them than over the healthy

* This is known as the "indifferent point," when *polar effects* are being studied at the other electrode.

† German authors employ different symbols from those given. These are as follows: C. C. C. = Ka S. Z., C. O. C. = Ka O. Z., A. C. C. = An S. Z., A. O. C. = An O. Z. The symbols Ka = cathode, An = anode, S = closure (*Schliessung*), O = opening (*Oeffnung*), Z = contraction (*Zuckung*).

muscles. This fact is due to atrophic changes in the muscles. It may be of decided value in diagnosis.

When disease processes in the brain or spinal cord cause

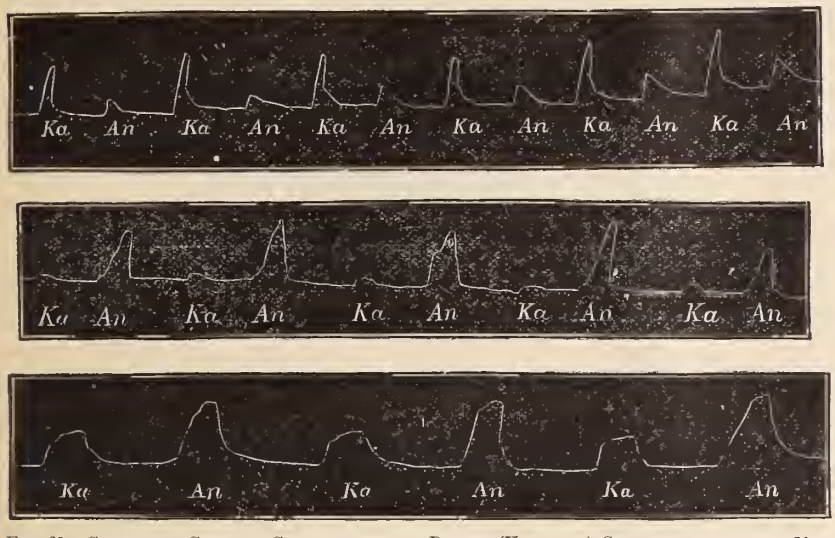

FIG. 32.—CURVES OF CLOSURE CONTRACTIONS IN DIRECT (UNIPOLAR) STIMULATION OF THE MUSCLES IN THE DISTRIBUTION OF THE PERONEAL NERVE IN THE LEG (Erb). Ka = C. C. C.; An = A. C. C. 1, Curve of health, thirty-three elements; C. C. C. is greater than A. C. C.; 2, case of chronic anterior poliomyelitis, showing reaction of degeneration with thirty-three elements; 3, same case, with forty elements. In 2 and 3, the excess of A. C. C. over C. C. C. is apparent; 3, in the slow character of the contractions is very marked.

destruction of the trophic centers of the nerves that supply the paralyzed muscles, or when the *cerebro-spinal nerves themselves are seriously injured*, we encounter what Erb has described as the "REACTION OF DEGENERATION." This will require some explanation.

1. *Every nerve degenerates when separated from its trophic center;* hence, the electric excitability of the nerve, both to the faradaic and galvanic currents, gradually diminishes and ceases entirely at the end of about two weeks.

2. The *faradaic current ceases to cause muscular contractions* when applied directly over the substance of the muscle. This is explained by the fact that the so-called "nerve-plates" within the substance of the muscle are degenerated, and currents of momentary duration fail to affect the muscular fibers.

3. The muscular contractions produced by the *galvanic current are diminished for about ten days.* Subsequently the excitability of the muscles *to slowly interrupted galvanic currents becomes increased*, so that very weak currents may excite contractions. This may disappear in five or six months.

4. The *polar reactions become altered in their sequence.* The anode contractions appear before those of the cathode, as shown below:

1.....	A. C. C.	instead of	C. C. C.	as in	health.
2.....	C. C. C.	"	A. C. C.	"	"
3.....	C. O. C.	"	A. O. C.	"	"
4.....	A. O. C.	"	C. O. C.	"	"

5. The *character of the muscular contractions becomes altered.* In health, they are sharp, short, and sudden. When degeneration occurs, they are slow to appear; they are prolonged and continue even during the passage of the current; and, finally, they assume the character of "tetanic" contractions, irrespective of the strength of the current employed.

Finally, in unilateral paralysis the electrical reactions of the muscles of the paralyzed side should be contrasted with those of homologous muscles of the unaffected side. When both sides are impaired, the standard of comparison should be that of a healthy subject of about the same size, weight, and muscular development.

Now let us suppose that we wish to test the reaction of some special nerve—the musculo-spiral, for example. We place the positive pole (An) of a galvanic battery over the breast-bone with a large flat electrode attached, and the negative pole (Ka) over the nerve (where it winds around the humerus below the deltoid muscle) with an "interrupting" small electrode attached to the negative rheophore. We then put into circuit a few cells at a time and press the button of the interrupting electrode at intervals till we get a contraction of muscles. When the current is sufficiently strong to excite the nerve-trunk, contraction of the extensor muscles of the forearm becomes apparent (the *cathodal closure contraction*). Thus we ascertain the number of cells required to produce C. C. C. (Ka S. Z. of the Germans). Now add a few more cells, and reverse the poles by means of the commutator. When the circuit is *broken*, by releasing the button of the interrupting electrode, we get the anodal opening contraction (A. O. C., or An O. Z.), and, with a few more cells, the anodal closure contraction (A. C. C., or An S. Z.). Again reverse the current, and add a few more cells. Now, on pressing the button of the interrupting electrode, we get a very intense cathodal closure contraction (C‴. C‴. C‴., or Ka S. Z‴.), and, on releasing it, the cathodal opening contraction (C. O. C., or Ka O. Z.) is developed, thus completing the chain of polar nerve-reactions.

You should bear in mind that the *polar nerve-reactions differ in their normal sequence from those of the muscles* when the electrode is placed over the "motor point" of the muscle tested.

NORMAL NERVE-REACTION.

C. C. C. > A. O. C. > A. C. C. > C. O. C.

NORMAL MUSCLE-REACTION.

C. C. C. > A. C. C. > A. O. C. > C. O. C.

The *final contraction* (C. O. C.) of each of these series is seldom seen, because the current required to produce it is too painful to be endured. *Fewer cells are required to cause muscular formulæ than those of a nerve-trunk.*

In recording the results of an electrical examination of nerve-trunks and muscles it is best to arrange the record-page so that the two sides of the body may be easily contrasted. The number of galvanic cells employed or the number of milliampères of current (as shown by a galvanometer) should also be specified, and the faradaic reaction of

homologous nerves or muscle should be stated for the purpose of comparison and for clinical deduction. We may follow with advantage some such plan as the following:

Name, ... Date, ... Age, ...

History of Case. See page .... of Case-Book.

Faradaic Tests.

	Right side.	Left side.	Extent of secondary coil employed. (In centimetres.)	Nerve tested. / Muscle tested.
Nerve-reactions.....				
Muscle-reactions				

Galvanic Tests.

	Right side.	Contraction produced.	Left side.	Nerve or muscle tested.
Nerve-reactions..	Cells.	C. C. C. A. O. C. A. C. C. C. O. C.	Cells or milliampères	nerve.
Muscle-reactions.		C. C. C. A. C. C. A. O. C. C. O. C.		muscle.

Slips of this character may be printed and kept on hand. They can be pasted into the case-book of the physician when filled out. The tests made at different dates can thus be compared with each other and the progress of each case determined.

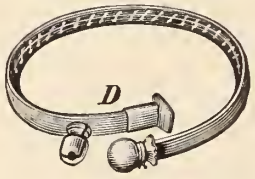

Fig. 33.—The Author's Spring Electrode.—*D*, the binding-post for attaching the rheophore which connects it with the battery, or with the diagnostic key-board when that instrument is employed. The motor point of the electrode is represented as enveloped in chamois-skin. It must be thoroughly dampened in salt-and-water before it is applied to the nerve or muscle to be tested The other end of the electrode is designed to prevent slipping of the instrument after its proper adjustment.

For the purpose of demonstrating the special action of individual muscles and nerves before classes of students, as well as the study of muscle- and nerve-reactions in disease, I have devised small electrodes which may be made stationary upon any desired part of the head, limbs, or trunk, by means of straps, strips of adhesive-plaster, or insulated springs. By means of these I have been enabled to make many points clear to a large audience which would be extremely difficult to show by any other method. Furthermore, it is often desirable to refer from time to time during an examination of a patient to the effects of currents of known intensity upon certain nerves and muscles for the sake of accurate comparison, etc. Small electrodes of the type described may be accurately placed upon a patient and allowed to remain upon the spot selected during the entire examination. To each of these a separate rheophore may be attached and, by a simple device of my own, each may be controlled by touching a key upon a board, without movement of the operator. I can thus observe simultaneously the reactions of corresponding muscles or nerves upon the

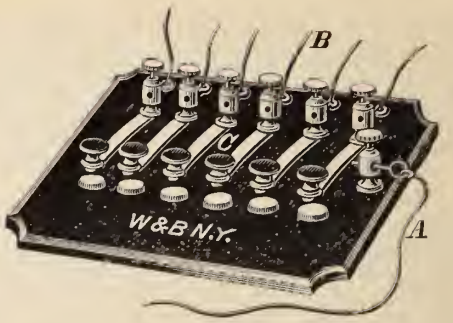

Fig. 34.—The Author's Diagnostic Key-board.—*A*, the rheophore which connects it with one of the binding-posts of a galvanic battery; *B*, rheophores connecting its binding-posts with spring electrodes previously placed upon the body of the patient so as to influence the nerves or muscles to be tested; *C*, buttons and springs which make a circuit to the body of the patient when the knob on the spring is pressed downward so as to impinge upon the button. The number of rheophores which may be employed depends upon the necessities of the case; the cut shows an instrument capable of six.

two sides, those of the leg and arm of the same side, and any other comparisons which may be required in diagnosis. The "motor-points" of the body are not always exactly where charts depict them; hence it is sometimes necessary to hunt for them within a radius of an inch or two of the normal point. When they are found with exactness, a small electrode may be fastened over the spot (with moistened absorbent cotton beneath it) and allowed to remain stationary during the entire sitting. Whenever it becomes necessary to refer to the reactions of that point, it can be called into action by touching the key connected with it by its individual rheophore. The cuts introduced show the arrangement of my device for this purpose. I have given a more complete description of the advantages of this method over others previously employed, in the "New York Medical Journal" of May 9, 1885.

Now, from such a table of record it is apparent that the *faradaic current should first be employed* upon the patient (the poles of the secondary coil being used). The extent of the overlap of this coil (in centimetres) necessary to produce muscular contractions when the nerve- and muscle-reactions are being separately tested should be recorded. In case no muscular contractions ensue, the extent of the overlap which produces an *unbearably painful current* should be ascertained and noted. This may be compared with that necessary to produce contractions upon the healthy side. The "polar method" should be employed in the tests thus made and recorded.

The next step in the examination consists in *changing the rheophores to the binding-posts of a galvanic battery.* We can now ascertain the number of cells or of milliampères (which is preferable) required to produce the different varieties of contractions (enumerated in the table designed for record) of muscles in homologous regions of the right and left sides. Each nerve which is impaired should be tested first; and the muscles supplied by it should be tested afterward. The strength of the current employed should be ascertained by throwing a galvanometer into the circuit

(when extreme accuracy is desired); by so doing, a comparison of the nerve- and muscle-reactions of the two sides can be based upon conditions which are exactly alike.

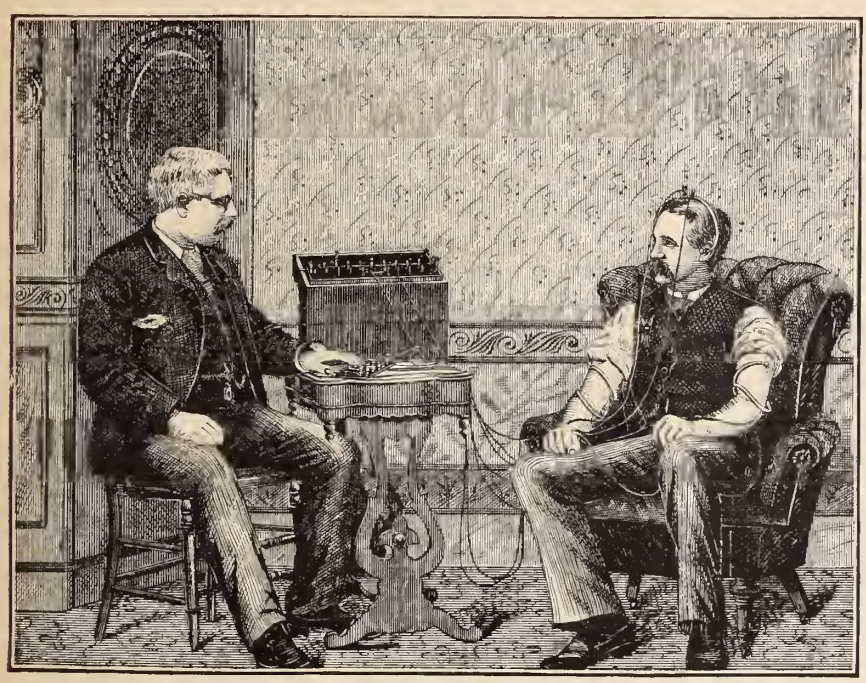

FIG. 35.—THE AUTHOR'S DIAGNOSTIC KEY-BOARD AS APPLIED IN ACTUAL USE. The spring electrodes are represented in the cut (for the purpose of illustration) as applied to the facial, ulnar, and musculo-spiral nerves of each side. If he chooses, the operator can have his case-book on a stand at his right, for recording his observations as they are made.

When we have completed the steps indicated by the chart prepared for the assistance of the beginner we are in possession of certain facts which may be of great practical value as regards both diagnosis and prognosis:

1. Suppose a case of localized paralysis is examined, and the faradaic and galvanic reactions of both a nerve and its muscles are normal and exactly alike on the two sides. We have reason then to believe that the exciting cause is either hysteria, a lesion of a higher spinal segment than that from which the nerve arises, or a lesion within the brain, provided the possibility of deception on the part of the patient respecting his paralytic condition can be excluded.

2. If the *nerve-reactions* of the affected side to both currents *are exaggerated* (i. e., if the contractions occur in their proper sequence, but under a weaker current than in health), the *probability of an existing central lesion is heightened*, although hysteria may possibly still exist as the exciting cause of the paralysis.

3. If the faradaic current applied through the nerve *fails to produce contractions* of the affected muscles as readily as upon the healthy side (i. e., if a stronger current is demanded to call any one of the paralyzed muscles into action indirectly through the nerve which supplies it), then we know that the *nerve filaments within the spinal cord* or the *trunk of the nerve itself* are affected by a lesion which *has impaired but not entirely destroyed their usefulness.*

4. If *no current* from a faradaic machine (which can be endured by the patient) *causes muscular contractions*, we know positively that the *motor cells of the anterior horns* of that spinal segment which controls the paralyzed muscles are destroyed, or that the *nerve itself has been severed* from its connection with the spinal cord.

5. When the MUSCLE-REACTIONS to the faradaic current have been tested, the previous deductions (based on the nerve-reactions) still hold good. The electrode should, however, be placed over the "motor point" of each muscle thus tested.

6. If the *formulæ obtained by the galvanic current are normal*, all questions regarding the existence of degenerative changes in the nerve- or the muscle-plates can be excluded. When the *normal order is altered*, degenerative changes in the nerve- or the motor-cells of the spinal cord are present.

7. The history of a case in which motility is impaired is never complete without a record of an electrical examination of the nerve- and muscle-reactions to both the faradaic and galvanic current. When doubt exists respecting the existence of a cerebral lesion or hysteria, the facts obtained by other methods of examination (fully described by me in the "Medical Record," March, April, and June, 1884) will clear up all doubts.

8. Patients afflicted with *paralysis from a cerebral lesion* generally exhibit normal electro-nerve and electro-muscular reactions in the paralyzed parts. In some instances the reactions may even be exaggerated.

9. *Hysterical patients* afflicted with paralysis may exhibit either normal or exaggerated electro-muscular reactions to faradism or galvanism. The sensitiveness of the muscles to faradism is generally decreased; in some cases it may be totally wanting (Duchenne).

10. In *rheumatic paralysis* the electro-muscular contractility is, as a rule, markedly increased; this may be shown by a comparison of the reactions of the two sides of the body. In exceptional cases this is not found to be so, as I have seen the reactions follow only the strongest currents.

11. In *peripheral paralysis* the faradaic and galvanic reactions are altered after ten days have elapsed. The muscular contractility to the faradaic current is lost early to a greater or less extent; and the formula of degenerative changes is developed later by the employment of the galvanic current.

12. A decreased musculo-excitability to the faradaic current in the musculo-spiral nerve and the extensor muscles of the forearm on both sides—the flexors being normal and the lower extremities being unaffected—tells us of the approach of *lead-poisoning* before the actual symptoms are well marked.

13. In *progressive muscular atrophy* a response to the faradaic current can be obtained as long as any fibers in the muscle tested remain free from fatty metamorphosis.

14. *No alterations* in the electro-contractility of muscles is observed in any of the diseases confined to the *posterior part of the spinal cord.*

DETECTION OF FEIGNED DISEASES.

In addition to the uses of electricity for the purpose of determining the presence or absence of nerve- and muscle-degeneration, and the discrimination between cerebral and spinal paralysis and the various types of peripheral palsies, some other useful purposes in diagnosis have been published from time to time.

The Detection of Death.—It is stated that muscular contractions produced by the faradaic current can not be maintained over four hours in a dead subject.

Malingerers are not uncommon among the applicants for charitable aid, and they are occasionally encountered among the higher walks of life. Epilepsy and paralysis are the most common diseases which are feigned.

Feigned epilepsy can be distinguished by the application of a strong faradaic current to the forehead or tibia by means of a wire-brush. The intense pain so produced will not be appreciated by a true epileptic, but will bring the fit to a sudden close, if assumed in order to create sympathy or aid.

Feigned motor paralysis is usually exhibited in some of the various forms of peripheral paralysis. Few malingerers know enough to simulate hemiplegia or paraplegia without detection. If two weeks have elapsed since the attack, the presence of normal electrical reactions of nerve and muscle in the affected limb is strong ground for suspicion, provided a history of some cerebral lesion or of hysteria can not be elicited. There are various other tests which a skilled anatomist can employ in each case that will help to clear up all doubts upon this subject.

Feigned anæsthesia may be told by the use of the faradaic current with the wire-brush attached to the negative rheophore. The opposed limbs will quickly show how much actual anæsthesia exists.

Detection of Bullets or Buried Metal.—An ingenious application of electricity to surgery has been made which has utility in diagnosis.

The so-called "*electric probe*" consists of two wires which are perfectly insulated from each other by rubber or ivory. These wires terminate in metal tips which project slightly beyond the insulating medium, and at the other end of the wires a galvanic cell and an electro-magnet acting upon a bell are attached. When the probe is pushed into the tract made by a metallic missile, and the tips are brought into contact with it, the circuit is completed and the bell rings. The animal tissues are not sufficiently good conductors of electricity to form a circuit; hence the bell will not ring until the metal is touched by the tips of the probe.

Electro-diagnosis of Aural Diseases.—We owe to Brenner, of St. Petersburg, the first suggestions of this use for electric currents in diagnosis. From a somewhat limited experience in its use, I am led to believe that its utility can not longer be called into question. Brenner's formula seems, furthermore, to be in accord with all that has been proved in respect to nerve-trunks in health, in all parts of the body. The formula is simply that of the galvanic reactions of the auditory nerve in health.

1. In place of the C. C. C. observed in muscle, we get, when a galvanic current is sent through the auditory nerve, a *ringing noise* when the *cathodal closure* occurs. (C. C. S.)

2. The *cathodal opening* produces no effect.

3. The *anodal opening produces a ringing noise* when a current of high intensity is employed.

4. After the cathodal closure (*cathodal duration*—C. D.), the ringing noise produced at the closure *gradually diminishes.*

The formula which is indicative of health when a pole is connected with each ear may be expressed in symbols, as follows:

	Right Ear (Anode).	Left Ear (Cathode).
C. (closure)....	.....	S. (loud)
O. (opening)....	S. (weak)	.....
D. (duration)...	.....	S. >

Now, it is maintained by Brenner that any deviation from the normal reactions of the auditory nerve (shown in the preceding formula) indicates disease of the acoustic mechanism. The variations produced by the different diseased conditions encountered can not be given here from want of space.

In applying galvanic currents to the ear, it is best to place a medium-sized electrode over the entire tragus or to fill the external auditory canal of the ear to be tested with tepid water containing a little salt, and then to introduce an electrode of metal inclosed in an aural speculum of hard rubber into the ear until the metal touches the water. If each ear is to be tested separately, the other electrode should be placed at an indifferent point, preferably the mastoid region of the same side or the middle of the sternum.

Regarding this test, it is well to state that repeated sittings are often necessary. The patient has to become accustomed to the disagreeable effects of the current. It is desirable that you begin with very weak currents and increase the strength very gradually. As the reaction of *cathodal closure* (C. C.) is the most important, it can be intensified by previously allowing cathodal duration (C. D.) to act, or by rapidly following C. C. by A. O.

Examination of the Eye, Nose, and Mouth by Electricity.—Special effects are produced upon the organs of sight, smell, and taste by electric currents. Sparks or vivid flashes of light follow electric stimulation of the eye; and subjective odors and tastes are also produced when the olfactory and gustatory nerves are excited by this agent. The "polar method" of examination is employed when any of the special senses are thus tested. I would caution each of you against employing too strong currents about any of the organs of special sense. The examination of the optic, olfactory, and gustatory nerves requires experience and should not be attempted by novices.

When examining the *reactions of the eye*, the small electrode is placed upon the closed eyelid, temple, or forehead. The large electrode is placed upon the back of the neck. The room should be darkened and the patient should keep both eyes closed.

When *testing the sense of taste*, the poles should be in contact with the cheeks, and the sensations of taste experienced upon both sides by the patient should be ascertained. A fine electrode can also be placed upon the tongue, the pharynx, or the inside of the cheek, in case localized polar reactions are to be determined. A double electrode, with two metal tips which are not in contact, may be employed for this purpose (Neumann).

Electrical Examination of the Sensibility of the Skin.—The electrode devised by Erb is to my mind the best for this purpose. It consists of four hundred varnished wires in a tube of hard rubber. The ends of these wires make a perfectly smooth surface. This electrode is connected with the secondary coil of a faradaic machine and is then pressed upon the area of the body to be tested—the other pole being at the sternum. The *minimum* of the overlap of the secondary coil which can be felt and the *maximum* which can be endured are both recorded. Homologous parts of each side should be compared with each other.

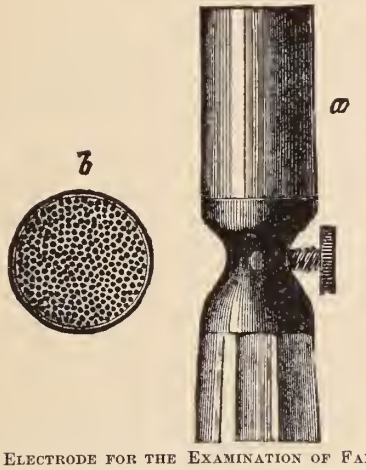

Fig. 36.—Erb's Electrode for the Examination of Farado-cutaneous Sensibility. *a*, a hard-rubber tube; *b*, the free surface of the electrode.

Regarding this test Erb wisely remarks: "The skin, regarded as a sensory organ, can not be tested with irritants other than those adequate to it—viz., touch, pressure, various temperatures, and the higher grades of those irritants which produce pain. It may be disputed whether electricity should be included among these 'adequate' irritants of the skin. The electric sensation is a specific, distinct quality of tegumentary sensibility, whose careful examination, however, is of value in many morbid conditions."

Original Communications.

ANTISEPTIC INHALATIONS.*

By BEVERLEY ROBINSON, M. D.

In a paper read before the Practitioners' Society of New York last winter, "On the Utility of Intra-pulmonary Injections in the Treatment of Pulmonary Phthisis," I said that I intended, at an early date to bring before my medical colleagues the subject of antiseptic inhalations. In the brief paper I now offer for your consideration I shall do this, but I shall not limit myself solely to the consideration of the advantages of these inhalations in pulmonary phthisis. Already I have made use of them in several affections of the respiratory tract—both acute and chronic. Although the cases treated by me in this manner are not yet numerous enough to afford a solid basis for final conclusions, they are at least sufficient to point distinctly to an extensive and beneficial trial of this method in a large class of respiratory diseases. The method is not new, it is old; but it is also a case of revival, with more precise data to establish its special indications and employment. To any one who has made frequent use of steam vapor inhalations, and hot or cold atomized fluids or sprays, the great advantages of the plan which forms the theme of this study, in the treatment of the affections referred to, is too real to be lightly considered or entirely ignored.

In its favor may be cited the following propositions:

1. The apparatus required costs but a trifle, and may be used, therefore, even by the poorest classes.

2. Medication thus applied may be employed under circumstances where the use of hot or cold sprays is impracticable.

3. There are no risks of future colds attendant upon its employment.

4. The relief afforded by dry vapor inhalations is, in my experience, frequently greater than that given by the other methods of inhalation.

5. This medication is well adapted to all forms of irritative disease of the respiratory passages.

I know of only one serious objection which can be properly urged against its very general adoption, and it is the statement that the vapors of volatile antiseptic substances, when they are employed in the ordinary oro-nasal inhaler, do not penetrate far enough to reach the pulmonary cells, and, therefore, can not possibly modify this structure in any sensible degree.

Upon experimental grounds, Arthur Hill Hassall ("Lancet," May 5, 1883) has endeavored to show that the agents most frequently employed hitherto—such as carbolic acid, creasote, thymol, etc.—are but feebly volatile at ordinary temperatures. He has also been unable, after prolonged inhalation, to recover any notable quantity of these substances in the sputa or secretions from the air-tract. In fact, he has not even remarked that the sputa, soon after they were expectorated, were penetrated with their odor. Indeed, after continuous inhalations of one or two hours' duration, he has succeeded in obtaining, by Chandelon's process, from the sponge or cotton in the inhaler, very nearly the whole quantity of the agent employed. A sufficient answer to these objections, it seems to me, may be found in the fact that the patients themselves, when questioned, after they have used the inhalations during a few days or weeks, as to their utility, almost invariably reply that their subjective symptoms have been notably relieved by them. Not only do they make this statement, but they add, further, that their sputa have di-

* Read before the American Climatological Association, May 27, 1885.

minished in quantity, and at times have notably changed in appearance. Moreover, while I am willing to admit that dry vapors do not enter the lungs so deeply as we might presume, or indeed as, theoretically, we might desire, yet they certainly do go further than the sprays for which they have been substituted. I am of the opinion, also, that the small loss of substance which has not been recovered, and which *possibly* does penetrate the pulmonary air-cells, is sufficient to modify notably, after several days or weeks of more or less continuous inhalation, the inspired air in such a manner that it is made comparatively aseptic, and thus we have an influence for good that we can properly estimate only by the evident effects produced. In regard to the areas of cough in the bronchial tubes, as in the lung itself, I believe something may be learned by reference, first, to my own experiments with intra-pulmonary injections, and, second, to the well-known facts recorded by Hack and J. N. Mackenzie in their investigations upon the nasal passages. In my experiments I was led to believe that *pulmonary cough* was largely due to irritation produced at the apices. And surely this conviction need not be a matter of surprise, since we all know that the sensitive area for cough in another organ (the nose), physiologically allied to the lungs, is not general, but limited almost to the posterior extremities of the turbinated bodies.

Again, is it not true that, in many cases where there is notable effusion into the air-cells at the pulmonary bases, as in œdema following chronic Bright's disease or organic heart disorders, there is usually little or no cough? Whenever, on the contrary, as in commencing bronchitis or phthisical infiltration, there are obvious morbid changes at the apices, what more obstinate and constant symptom can be observed than the ceaseless racking cough? Finally, I have on more than one occasion, I am confident, punctured the lung deeply in searching for pleuritic fluid, either posteriorly or in the axillary line, as was evident by the blood and air withdrawn into the cylinder of the hypodermic syringe, or into the pump of the aspirator, and cough has not followed invariably. This fact is, however, also true in regard to punctures at the pulmonary apices; but here the intra-pulmonary alterations have been very different from what existed at the bases at the time punctures were there made. In the former cases the lungs were already infiltrated with tubercles which blocked up the bronchi and surrounded their periphery; in the latter cases the bronchial tubes were inflamed or compressed, it is true, but were not, as a rule, completely impervious to air. Mucus and serum, blood-streaked or not, they usually contained, no doubt, but even then their condition was such as to render them *a priori* more sensitive than they should be under wholly normal circumstances.

I will now place before you some of the results of my trials with dry vapor inhalations up to the present time, and if, by their analysis, I can prove the utility of this method clinically, I shall hope to stimulate further inquiry, and persuade many of you to give it the opportunity which, I believe, it merits. It is understood, I assume, that I do not claim any originality for the treatment of my cases. These dry inhalations were reintroduced to the profession, as you are all aware, some years ago by Dr. W. Roberts, of Manchester, England, and since that time have been more or less extensively employed by H. Curschmann, of Hamburg, and by several other able practitioners at home and abroad. Among these I would cite particularly William Pepper, in the "Transactions of the American Medical Association" for 1880; J. H. Tyndale, New York "Medical Record," March 18, 1882; J. Burney Yeo, in his "Lectures on Consumption," London, 1882; S. S. Cohen, in Philadelphia "Medical News," October 11, 1884; J. Ward Cousins, "Lancet," July 19, 1884; and A. Hill Hassall, "Lancet," August 16, 1884, and "Inhalation Treatment," London, 1885.

The following summary shows the number and nature of the cases of which I have preserved notes, but does not represent one half the number of patients for whom I have ordered oro-nasal inhalers. I regret to add that, even in those cases of which I possess a record, several were not studied with much care, and, consequently, my remembrance of the results obtained is very imperfect. A sufficient number remain, fortunately, in which I have watched carefully the effects of dry inhalations, and about whose condition, before and after their use, I can speak with more assurance.

My tabular statement includes twenty-two cases of phthisis pulmonalis, catarrhal or tubercular, at its first stage, or when already there were evident and characteristic signs of tissue infiltration.

In four of these cases there were marked local pleuritic adhesions. In the remaining cases no statement is made other than the fact that pulmonary consolidation at the apex or apices was present.

Nineteen cases of pulmonary phthisis, catarrhal or tubercular, at its second stage, were treated partly by means of oro-nasal inhalers. Of these nineteen cases, in eleven the softening was limited to one apex; in two cases both apices were thus affected, while in the other cases no reference is made to the limitations of the disease. There were six cases of fibroid phthisis treated by inhalers; three cases of laryngeal phthisis, in one of which there was commencing carious ulceration of the vocal cords. There were two cases of acute laryngitis, seven cases of subacute laryngitis, three cases of chronic laryngitis, two cases of subacute bronchitis, three cases of chronic bronchitis, five cases of chronic nasal catarrh, four of which were of the hypertrophic form, the remaining one being distinctly atrophic catarrh, with which were connected a condition of pharyngitis sicca and a notable degree of fœtid odor of the breath (ozæna). I also treated in this manner one case of chronic pharyngitis, two cases of localized pleuritis, and one of paralysis of the tensors of the vocal cords—the total making *seventy-six* cases which form the basis of the remarks I shall make before you to-day.

First, in regard to pulmonary phthisis at its first stage. Of this disease I have the records of twenty-two cases in which I used dry vapors. The inhalations consisted of, 1, creasote and alcohol equal parts; 2, creasote one part, ol. pini sylvestris two parts, and compound tincture of benzoin eight parts; 3, compound tincture of benzoin; 4, fir-wood oil; 5, fir-wood oil sixteen parts, creasote one part; 6, fir-wood oil six parts, chloroform two parts; 7, creasote one

part, fir-wood oil sixteen parts; 8, compound tincture of benzoin and fir-wood oil, equal parts; 9, spirits of turpentine; 10, volatile oil of eucalyptus; 11, carbolic acid and tincture of iodine, of each one part, compound tincture of benzoin eight parts; 12, fir-wood oil one part, succus conii and compound tincture of benzoin, of each two parts, carbonate of magnesium, q. s., water eight parts; 13, pine-needle oil; 14, terebene four parts, spirits of chloroform one part.

It will be remarked that I varied considerably the nature and composition of the substances employed for inhalations—and this is specially notable if the limited number of my cases be considered. I made these trials advisedly, as I was very desirous to find out not only if vapor inhalations were useful, but, indeed, if certain combinations were more effective than others under similar conditions.

The results of my observations would seem to show that the most generally useful inhalation in the beginning of pulmonary phthisis is creasote and alcohol, equal parts. Creasote by itself is a little too irritant, and is not so readily manipulated. Whether or not the mixture of alcohol increases its volatility I am not positive, although I believe it does, regard being paid to the statements of patients. The amount of inhaling fluid employed with best results varied from ten to twenty drops. It was also renewed most advantageously two or three times in twenty-four hours. The inhalations were employed at first about ten minutes every two, three, or four hours. After a week or two they could be continued, without unpleasant effects, one half or one hour at a time, and repeated three or four times in twenty-four hours. If a larger quantity of the inhaling fluid was used at first on the sponge of the inhaler, or if at first the time for each inhalation was extended beyond fifteen minutes, the patient suffered from irritation of the throat and increased painful cough on several occasions. The form of inhaler employed by me was usually one not dissimilar in outward conformation to that employed by Burney Yeo, of London, and S. S. Cohen, of Philadelphia. It may be of interest in this connection to give a short account of the different oro-nasal inhalers in use at the present time. Some of these are shaped so as to cover the mouth alone, some are adapted simply to inhalation through the nose, and some encircle both nose and mouth. They are made of metal, hard rubber, or celluloid, and are usually constructed from a single sheet of the material employed, their particular shape being made to suit the requirements of the majority of individuals. In Blake's and Tyndale's inhalers, which cover both nose and mouth, there is a circular valvular opening on either side, about one third of an inch in diameter, which closes by means of a soft rubber flap that rises or falls with each inspiration or expiration, and is intended to promote the facility of expiration and to avoid the passage of respired air through the sponge charged with the inhaling fluid. In Hassall's oro-nasal globe inhaler similar valvular openings on the sides have been provided, and this inhaler has the additional advantage, as stated by its inventor, of supplying a larger amount of medicated vapor to the patient for purposes of inhalation. This result is effected by reason of the considerable capacity of the globe itself for containing bits of lint moistened with a suitable amount of inhaling fluid, and owing to the wider orifice of communication between the globe and the oro-nasal piece, or shield, which allows plenty of medicated vapor to pass through and be inhaled with each inspiration. When an inhaler is fitted to the nose alone, it is better, as a rule, for the patient to expire through the mouth than through the nose, as in this way a more complete circuit of the nasal passages by the vapor is accomplished than if expiration took place through the nose. None of the inhalers described, although somewhat more elaborate and expensive, seem to me so useful as the cheap and simple one here shown. This one, as you perceive, is made of a thin sheet of perforated zinc; it is extremely light, and may be worn, therefore, a long time without causing the fatigue to the patient which the other inhalers often do. It also permits the air to pass freely in and out, and thus obviates almost entirely the sensation of oppression and stifling, which is apt to make the prolonged use of the other oro-nasal inhalers almost impossible.

One of the objections urged against the efficacy of most oro-nasal inhalers is the fact that too small a supply of vapor is given off from the small bit of sponge, cotton, or tow which comes with them to be of any benefit to the patient. In the globe inhaler Dr. Hassall has remedied this supposed defect. For my part, I have not usually found it a defect, and I have rarely found the slightest difficulty in supplying my patients, by means of the perforated zinc inhaler, with all the medicated vapor they could comfortably endure. Indeed, I have observed several times, as other observers have done before me, that the quantity of antiseptic liquid added to the sponge of the inhaler must be limited to a few drops (10 to 20) if the inhaler is worn more than a short time. If a relatively large quantity of antiseptic fluid be added to the sponge, the vapors proceeding from it are too concentrated and shortly become very irritating to the air-passages, and the inhaler must be abandoned. Instead of doing good, therefore, by adopting the latter manner of medicating the sponge of the inhaler, we actually do harm and render a very serviceable agent a decidedly objectionable one. I am therefore not of the opinion of Dr. Hassall as regards this point in inhalation—viz., that with the ordinary forms of oro-nasal inhalers we do not volatilize a sufficient quantity of antiseptic fluid to be of service as an inhalant; and even when we volatilize enough fluid not enough antiseptic vapor is inhaled to modify the air-cells to any notable degree.

(To be concluded.)

TWO VALUABLE AIDS TO ELECTRO-THERAPEUTICS.

By LANDON CARTER GRAY, M. D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASE, NEW YORK POLYCLINIC; ATTENDING PHYSICIAN TO ST. MARY'S HOSPITAL; ATTENDING PHYSICIAN TO THE HOSPITAL FOR NERVOUS AND MENTAL DISEASE.

One of the greatest of the difficulties that have been encountered by the electro-therapeutist has been the lack of a suitable galvanic battery. Of good faradaic machines there has been no dearth, especially since the invention of the cheap and portable apparatus made by Gaiffe, of Paris.

But the galvanic batteries for general use have been unpleasantly heavy, and the Grenet cell, or some modification of it, which has been mostly employed in them, is a constant source of annoyance from the necessity of frequent renewal of the plates and still more frequent renewal of the fluid. I have therefore, for years, been on the search for some combination of elements that would be portable and durable in a far greater degree than the Grenet cell. My attention was called to the fact that Gaiffe was constructing a battery with the chloride-of-silver elements that seemed to answer the requirements; but the importation was costly and troublesome, and the cells had to be sent to Paris for renewal. Dr. De Watteville, of London, very kindly put me in communication with Mr. Schoth, an instrument-maker of London, who had been experimenting with the same cells at Dr. De Watteville's instance; but Mr. Schoth had not yet constructed a battery with them. Finally I ascertained that Mr. John A. Barrett, a New York electrician, was making a battery with these cells. This instrument I have now been using daily for some five months, and I am prepared to say that its general employment will mark a new era in galvano-therapy. The cut (Fig. 1) gives

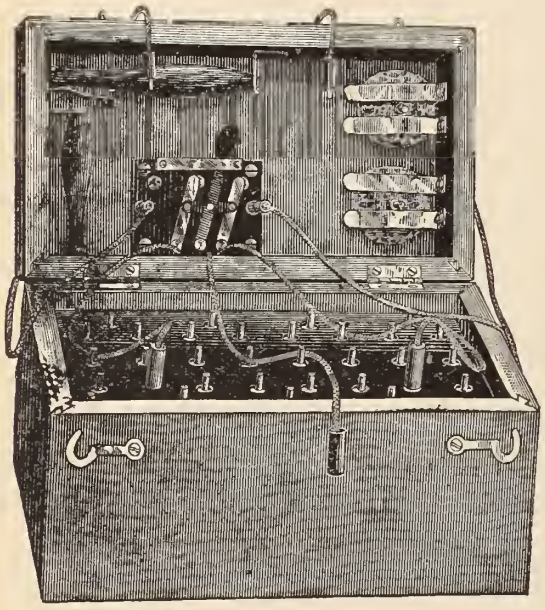

Fig. 1.

some idea of the size of the battery, but a better one can be obtained from the statement that an instrument containing thirty-two cells will only measure ten inches in length and weigh only nine pounds, while a fifty-cell one will measure twelve and a half inches and weigh twelve pounds. As will be perceived by electro-therapeutists, such a battery is by all odds the lightest that has yet been constructed. As to its durability, it is calculated that each cell will stand two hours' steady work daily for nine months, or a proportionate length of time otherwise arranged, before the elements will need renewal. Practically, therefore, such a cell will last the general practitioner a year or more, and the cost of renewal will be about eight dollars.

The details of construction are as follows: The cells consist of cylindrical bottles of black rubber. These bottles are fitted with screw stoppers or caps of the same material, which are fastened permanently to the underside of a black rubber plate. The elements, zinc and chloride of silver, are fastened to silver wires which pass in pairs up through suitable perforations in the caps and plate, and are attached on the

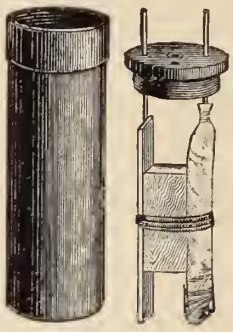

Fig. 2.

upper surface of the plate to fixed studs or pins so arranged that the zinc and silver poles of the successive cells are connected together through the entire battery. The bottles

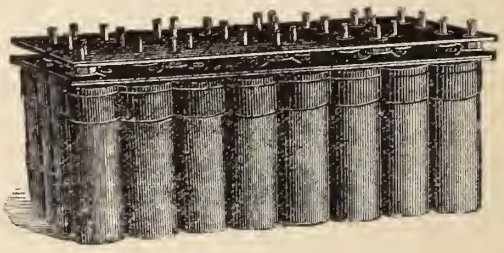

Fig. 3.

are partly filled with solution and are screwed from underneath to the caps, each bottle inclosing a pair of elements. The bottom of each bottle is provided with a slot, so that by a key the bottles may be screwed tightly to their caps. By this means the entire set of bottles is rigidly attached in an upright position to the plate, and at the same time any bottle may be removed independently of the others and its pair of elements examined, or removed and replaced, without inconvenience. Besides this, all the connections, being on the upper side of the plate, are easy of access and out of the reach of corrosion. The battery, thus prepared, is placed in a box, and a top-plate, perforated to fit the connecting studs, is laid over it. This top-plate is numbered for convenience in making connections. It is easily removable, and the whole battery may be readily lifted out of the box. In the lid of the box is placed a commutator or pole-changer, to which are attached short flexible cords terminating in hollow plugs. By these plugs any number of cells may be selected from any part of the battery. The pole-changer is also provided with two binding-posts, to which the conducting cords are to be attached. In the lid of the box are also springs for holding a pair of electrodes and handles. The strength of the battery is very nearly equal — within $\frac{1}{200}$ — to the same number of Daniell or blue-vitriol cells, and is maintained undiminished until the material is exhausted.

The instrument which, as I have already said, I have had in daily use for some five months, and which has many days been jolted about in my carriage over rough city streets

for five or six hours at a time, has maintained its current unimpaired in quantity or quality.

Another great need of the electro-therapeutist has been some means of measuring the quantity of electricity—something that will answer to the balance of the apothecary. It is quite usual to hear those using electricity speak of giving the patient so many cells for such a contingency and so many cells for another, which is just about as sensible as it would be to advise a man to wear so many coats in the Arctic zone and so many in the Antaretic, without specifying the texture that shall make up each individual coat. The sine and tangent galvanometers, which are used by those employing electricity in the arts, are too cumbrous and expensive for medical needs. Gaiffe, Böttcher, Stöhrer, Edelmann, and Hirschmann have each devised an absolute galvanometer. Of these, the ones constructed by Gaiffe and Hirschmann have been the best. Dr. De Watteville enthusiastically indorses the former, while others allege that it is faulty. Hirschmann's instrument has been well described by Dr. B. Sachs.* I have had no experience with it, but it appears to me to be complicated, and Dr. Sachs, after a year's use of it, states that "it does not bear transportation well, and the return of the needle to the zero point is slightly impeded by the action of friction." It seems, however, barring these disadvantages, to be a good instrument. The cost seems to me to be the main drawback to it. There has lately been constructed in this city an absolute galvanometer which is superior, in my opinion, to any other for the purposes of the electro-therapeutist. A cut is

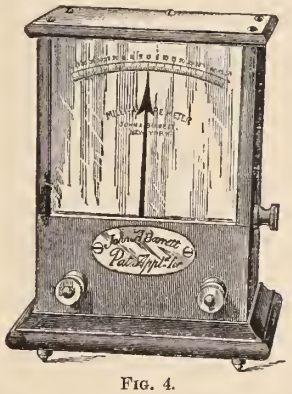

Fig. 4.

herewith appended. The unit of measurement is the milliampère—a unit which has lately come into use for medical purposes. It was first suggested in 1878 by Dr. De Watteville, and was adopted by the special committee of the International Congress of Electricians. It represents the current given by three Daniell's cells through the average resistance of the human body, and medical currents range in strength from one to fifty of these units.

The scale is graduated from one to fifty of these new units. The working parts of the meter are inclosed in a case about four inches square at the base and six inches high, having a glass face, showing the pointer and scale. The pointer is attached to the movable magnetic needle, which is a steel disc suspended within a surrounding coil of wire on two knife-edges, so as to oscillate freely in a vertical plane. The movements of the magnet are indicated by the pointer on the scale. The magnet is counterbalanced and held in equilibrium, so that the pointer rests at zero, by means of a small weight fixed to it below the center of gravity. These are so arranged that the position of the instrument relatively to the earth's magnetic poles is of no account. The magnet, being so poised on frictionless knife-edges, would be subject to prolonged and troublesome oscillations; but a dampening device is provided which consists of a vane or fan of thin mica, extended upward from the magnet in the back part of the case by means of a light, rigid stem of aluminium. This vane moves broadside against the confined air and brings the needle quickly to rest in any position, without, in the smallest degree, interfering with its sensitiveness. A locking arrangement also forms a part of the instrument, by which the magnet may be lifted from its bearings and fixed in an immovable position. By this means the knife-edges and movable parts are protected from damage during transportation and when not in use. A leveling screw is placed on one side below, so that the instrument may readily be adjusted to a proper position.

In use, the meter is placed in the circuit with the body of the patient, so that all the current which flows through the body flows also through the meter. In this situation the pointer of the instrument gives a deflection which measures in absolute units the current actually passing and doing work in the body.

The luxury of such an instrument can hardly be overestimated by any one making daily applications of electricity and desiring to work rapidly and precisely. For example, a patient comes to you to-day, and you find that you can employ twelve cells of your battery with no unpleasant effect. To-morrow he comes to you again, and, to your surprise, you find that you need twenty-four cells to obtain the same effect. The third day he comes still again, and squirms with pain when you turn on more than six cells. Your milliampère-meter solves the mystery. It tells you that all the time your patient has borne about ten or fifteen milliampères of electricity, and that the daily differences have been due to variations in the conductivity of the skin, moisture in your sponges, heat of the moisture, etc.

* "Jour. of Nerv. and Ment. Dis.," vol. xii, No. 1, Jan., 1885.

IMMUNITY IN DISEASE.

By ROMAINE J. CURTISS, M. D., Joliet, Ill.,
PROFESSOR OF HYGIENE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

(*Concluded from page 42.*)

One of the more important correlatives of the immunity from disease given by natural selection is the history of the great epidemics of plague, black-death, typhus, etc. These epidemics, during the dark ages, killed millions of people, and were prevalent more or less continually. These diseases were not conquered by sanitation. An epidemic nowadays makes just as violent a warfare in Europe as epidemics ever did, provided there is no acquired physical resistance of tissue-cells to the poison of the germ. But the old epidemics lost their power and declined, and finally became

practically extinct. Efforts have been made to attribute this extinction to sanitation. The London fire has been given the credit of conquering the sweating-sickness, and the suppression of typhus and scurvy as epidemics has been ascribed to the efforts of John Howard and Captain Cook; but if cleanliness, or alleged cleanliness, or prevention of putrefaction, has cleaned out leprosy, black-death, jail-fever, etc., why are not cholera, typhoid, diphtheria, scarlatina, and other zymotics also subdued by the same alleged cleanliness? I think the only method of explaining the cessation of the old epidemics is the method of natural selection. When the epidemics prevailed, the germs, by combat with tissue-cells, caused a variation in the cells. The persons who acquired and maintained this variation transmitted it to their children. In time there was built up a community of people who had the power of resisting the germs of these epidemics, and the epidemics died out.

I think we may apply this action of natural selection in the community, as it is seen to subdue epidemics, to the person, in order to explain the self-limitation of disease, both limitation in duration of time and the limitation of disease of different kinds to corresponding organs or tissues. Syphilis appears not to be limited to any definite time, nor to any particular tissue or organ. Probably, next to syphilis, tuberculosis meets with less resistance among cells, and has less evidence of being self-limited in time. There is evidence, however, that both of these diseases are subject to the general law of limitation in both time and successful antagonism from certain tissues. Syphilis is certainly less violent than formerly. Modern authors speak freely on this subject. This is not because treatment has improved, for the treatment is the same now as when syphilis was almost certain death. It is because the whole of Christendom is syphilized, and natural selection is bringing the races of men out of the bonds of this disease. The various tissues of the body are acquiring a power of resistance to the syphilis germ and its poison, and transmitting this power of resistance by heredity. If one tissue after another of the body aequires a resistance to the poison, it is a *sequitur* that in time the tissue which is the last to acquire the resistance will show the only signs and symptoms of the disease. Syphilis will then be more limited in point of diffusion throughout the body, and must necessarily be of shorter duration. It will then present, in this respect, the characters of those diseases which are limited to certain tissues, and to a more definite period of time, notably typhoid, scarlatina, measles, small-pox, etc.

But another feature of the question is that the development of organisms is a resultant of actions and interactions between them, so far as they are related to each other. When the struggle for life is limited to a struggle between organisms, the variation is not limited to one of the combatants alone. Each gets a share of the variation. If the animal attacked by a micro-organism acquires a variation giving it greater resistance, it is likely that the attacking organism by this means acquires greater virulence. The "survival" in such a case bears direct relation to the organism which has the greater resources. That the human species exists to-day is proof enough that humanity at large is able to survive in spite of the enemies which cause disease; and that the species survives by reason of natural selection would appear to be clear enough. The defense appears to be a variation of the cells in their power to resist a poison, while the variation in the disease organism is an increase in its virulence. The variation of the species of micro-organisms by natural selection is a verified fact, and upon it depend all the benefits derived from inoculation. If the pathogenic organism of hydrophobia is bred in the bodies of certain lower animals, it loses virulence. There can be no method of accounting for this fact except that the tissue-cells of the animal have less resistance than those of the other animals which have given the organism its greater virulence. The *Bacillus anthracis* is modified in the same manner by artificial cultivation. On the other hand, reliable experimenters have determined that *B. subtilis* (hay bacillus) can, by cultivation and inoculation, be changed to *B. anthracis*. This variation of the species produces corresponding varieties in disease, and is the fact that underlies the immunity to disease which is brought about by vaccination or inoculation. There are several methods of producing these varieties, such as cultivation, dilution, attenuation, washing, etc. If natural selection can not explain these various methods, I do not know what will or can. The organism, varied from the type of its species in this way, as a general thing, is unable to cause disease by entrance into the body in the usual way, but depends upon accident. The accident must include an injury to the tissues or cells such as obtains in inoculation. When a wound is made the cells are destroyed. Most organisms are proof against septic bacteria unless there is a wound. Human beings have outgrown, or rather out-developed, septic bacteria, unless their invasion is preceded by an accident which causes a wound. Wounded cells and tissues have lost their power of physical resistance.

Another feature of inoculation is that the artificial method of gaining a foothold inside the resistance of the organism subject to disease, by means of inoculation, has the effect of shortening the period of incubation. This is true of inoculations of all varieties of pathogenic organisms. It is, therefore, an inference and a verified truth that vaccination may prevent small-pox, even after exposure to the latter. To deny the proposition is to deny that the period of incubation is shorter in vaccination than in small-pox, and the denial is also, by antithesis, an assertion that kine-pox will not prevent small-pox.

Dr. Eccles's inference from his own data, as well as from the facts here expressed, that the treatment of small-pox by vaccination, or vaccination after exposure to small-pox, is like treating strychnine poisoning by another dose of strychnine, is one of the most stupendous instances of logical *non sequitur* to be found in medical literature. In order to draw a like inference from different propositions, the terms of the propositions must have some relations of likeness. In Dr. Eccles's inference and statements there is no shadow of likeness. He must first prove that the incubation of small-pox from exposure is equal in time to that of vaccination, and also that vaccination will not prevent small-pox. If he had said that infecting the blood of

a small-pox patient with more small-pox poison was like treating strychnine poisoning with more strychnine, the terms of his proposition would have had more analogy. Testimony shows that vaccination is good medical treatment for small-pox, and, while the fact remains that kine-pox can prevent small-pox, the inference will be unavoidable that the germs of each, in relation to the host and the disease, are antagonistic physiologically—as much so as atropine and morphine. Their antagonism may depend upon the priority of their invasion of tissues. Their difference is the degree of virulence of each, but in relation to the tissues either is the antagonist of the other.

But Dr. Eccles's hypothesis, or absurdity, can be used to good purpose. Suppose that on a future given day a person is condemned to swallow a given poisonous dose of strychnine, or arsenic, or morphine, and wishes to prepare for it. In such a case the best method for the person will be to accustom himself to the use of the poison. If Socrates had known the relations of natural selection to the action of poisons, he might have drank his hemlock with no less grandeur and have saved his life. Dr. Eccles simply inverts the terms of natural selection in relation to poisons. His proposition looks formidable and strange. It reminds one of the man who tried to frighten a bull by standing on his head with his feet in the air. The man's appearance was unique, if not frightful, but was no protection against penetrating horns, backed by the fury of the Durham.

I think the hypothesis that immunity from disease is acquired by the interactions of tissue-cells and the pathogenic organisms of disease is one that can explain all phenomena of disease in this relation. Natural selection is one of the *verœ causœ* in nature. To further establish this hypothesis, it is, of course, necessary to examine other hypotheses to find if they will stand the test.

The hypothesis that a chemical compound is formed by the micro-organisms, and left in the tissues, which prevents their further action—as alcohol kills yeast, or acetic acid kills *Mycoderma aceti*, and as the excremental products of all bacteria destroy the organisms which produce them—is certainly unable to explain anything. If it were true, nothing could be easier to find in the tissues, and no such thing has been found. That destruction of certain tissues for which the parasite has an affinity gives the immunity is destroyed as an hypothesis for the reason that such tissues are repaired by the recovery of the patient, in all cases.

The oxygen theory of Dr. Salmon is too narrow a conception for the occasion, and there are no verifications to sustain it. Who can imagine that tubercle bacilli in the lungs can consume the oxygen inhaled so rapidly that there is not a sufficient supply for the lungs? The inhalation of oxygen is found to do harm in consumption as well as many other diseases. If Dr. Salmon's hypothesis is true, the inhalation of oxygen ought to not only cure, but prevent all diseases of zymotic origin. Let us transfer the terms of Dr. Salmon's proposition to another case. The terms are these as quoted from Dr. Eccles's paper: "The poison of the microbes intoxicates the cells. Retarded function [of the cells] allows oxygen to increase in the circulation, thus facilitating their gaining a foothold. Recovery is due to the ability of the cells to resist the poison [this is true, and all there is of it in relation to recovery and also to immunity], use up their own oxygen, and so asphyxiate the microbes." Dr. Salmon has not made an estimate relating to the ventilation of the human body with oxygen and the relative amount consumed by microbes and cells, which is necessary as a factor of this problem. It is quite likely that oxygen cuts no figure in the problem except as a necessary antecedent to all phenomena of life—microbic and human. I will transfer the terms of this problem to another case like it. Suppose a man and dog are confined in a well-ventilated room, and the dog, being hungry, attempts to kill the man to eat him. It is necessary to kill him first. The dog attacks the man, and, getting him by the throat, chokes him. Now the retarded function [of the man] allows the oxygen in the room to accumulate or increase in the room, thus allowing the dog to maintain his position. Now, if the man recovers, it is due to his ability to overcome the dog's hold on his throat, and then to use up his own oxygen, and by so doing asphyxiate the dog—by using all the oxygen himself. Dr. Salmon admits the solution of the question by natural selection when he says the "recovery is due to the ability of the cells to resist the poison." Immunity is also due to the same fact. The oxygen theory is therefore only a rider to the true solution; very much such a rider, too, as Mazeppa was, in so far as ability to guide the horse is concerned. Dr. Salmon's theory assumes that the microbes are in the body by accident, and destroy the cells, not to consume them, but in order to rob them of oxygen. The position of the microbe is that of offense rather than of defense.

It is evident that we can substitute nitrogen or bile in place of the oxygen in this problem and do no violence to the sense or the results. What prompts the dog in the assault is the necessity for food. The same is true with the microbes. The dog does not poison his prey, because he kills it mechanically; but this does not change matters any. The man may have some knowledge of dog-combat, gained from former experience, or may not; but, if he saves his life, it is not because he uses the oxygen in a well-ventilated room himself at the expense of the dog, but because he knows or learns a method of successful physical resistance to the dog. If he learns a specific method of resistance to the dog from actual combat, as punching the dog's eyes, or choking him, in time, doubtless, he will tell his children the method, and so transmit the gift by heredity to them, and the dogs will all be obliged to take up with Mother Hubbard, who, by this time, should have a bone or two in her cupboard.

The cell and microbe and man and dog present problems of warfare the terms of which are parallel and alike. The combat in each case is due to that great biological law which underlies all the sin of this world, which is that living things are adapted to each other as a food-supply, and the fittest will swallow the other. When Eve ate the apple, the probable extent of the sin was in the consumption of other living material. This would have been a guileless world if all living things had been created to take their diet from the inorganic world, and men "at meat" could sit

down to a table spread with samples from the inorganic world—nitrogen, ammonia, carbonic acid, salines, and water, instead of quail on toast, oysters, eggs, milk, lamb, chicken, etc.

In both these cases of man and dog, cell and microbe, we find corresponding and like general principles which explain all such cases. These combats result in variation of all organisms concerned. No case can be mentioned which can not be explained by this generalization. The variation consists in an organic change with corresponding functions in all organisms concerned. If the cells gain an immunity from further attacks of microbes, it is because variation, acquired by actual combat, has given them a power of physico-vital resistance to poison, which they maintain until the forces of atavism have taken this power away. The phenomena of immunity, in point of duration, correspond directly with the forces of variation and atavism. That we are unable to know the character of the variation and atavism which gives a cell the power to resist a poison, or makes it susceptible to poison, proves nothing against the hypothesis, but only proves that, for physical reasons, the verification is difficult.

But, while on the subject of immunity from disease, it is well to take a look at it from the standpoint of hygiene. The study of physically acquired immunity from disease is interesting only as a means or end of scientific accomplishment, and is of no great practical value. The science which can give a man immunity from disease only by subjecting him to an actual combat for life with his personal enemies is a science which is not worthy of being called hygienic. Why not destroy the microbe before it attacks the man, and gain the immunity by this means? Immunity gained through actual disease reminds one of the subject who went to his king and complained that his enemy had threatened to kill him. The King said: "Don't worry, my man; if he kills you I will have him beheaded within an hour." The man tried to appear comforted, but finally ventured to suggest that the best preventive would be to behead the enemy an hour before he made the threatened assault.

Immunity from disease, gained by costly combat with poisonous microbes, is the method of nature without intelligence. The method is not worth imitation except provisionally. The study of the microbe in this relation is useful only as it will give the knowledge of the methods which can compass its destruction while it is yet outside the body and before disease is produced.

Book Notices.

An Introduction to Pathology and Morbid Anatomy. By T. Henry Green, M. D. Lond., etc. Fifth American from the sixth revised and enlarged English edition. With one hundred and fifty engravings. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xx–17 to 481, inclusive.

An extended review of such a well-known book is unnecessary. We had already regarded the work as a model of its kind, and the author's assurance that he believes the present edition to be fully up to date will be received as sufficient proof that nothing of importance has been omitted. The reader will find several additions to the last edition. The introductory chapter has been remodeled, a new chapter on tumors appears, and the subjects of septicæmia and pyæmia are presented in an unusually clear and compact form. For these improvements the author expresses his obligations to his surgical colleague, Mr. Stanley Boyd. The closing chapter, upon "The Vegetable Parasites," appears beneath that gentleman's name, and is a thorough and exhaustive *résumé* of the subject. Appended to this section is a brief description of the different methods of cultivating and staining micro-organisms. In stating that the book is up to the time, we need not add that the bacilli of tuberculosis, cholera, and leprosy, and the micrococci found in erysipelas, pneumonia, scarlatina, typhus, and gonorrhœa, all receive due notice. The book has been most carefully revised, and bears upon every page the marks of that care and accuracy which have won for it an international reputation.

BOOKS AND PAMPHLETS RECEIVED.

A Text-Book of Medical Physics. For the Use of Students and Practitioners of Medicine. By John C. Draper, M. D., LL. D., Professor of Chemistry and Physics in the Medical Department of the University of New York, etc. With Three Hundred and Seventy-seven Illustrations. Philadelphia: Lea Brothers & Co., 1885. Pp. 733.

A Manual of Human Physiology, including Histology and Microscopical Anatomy; with Special Reference to the Requirements of Practical Medicine. By Dr. L. Landois, Professor of Physiology and Director of the Physiological Institute, University of Greifswald. Translated from the Fourth German Edition, with Additions, by William Stirling, M. D., Sc. D., Regius Professor of the Institutes of Medicine, or Physiology, in the University of Aberdeen. With 318 Illustrations. Vol. II. Philadelphia: P. Blakiston, Son & Co., 1885. Pp. xvi–515 to 1184, inclusive. [Price, $5.50.]

Berlin as a Medical Centre. A Guide for American Practitioners and Students. By Horatio R. Bigelow, M. D., Member of the American Medical Association, etc. [Reprinted from the "New England Medical Monthly."]

Report of the Board of Managers of the Pennsylvania Hospital, 1885.

Correspondence.

LETTER FROM ST. LOUIS.

Railway Sanitation.—The Inspection of Meat.—The Closure of Wells.

St. Louis, *June 30, 1885.*

Among the matters of importance to the public in regard to general sanitation and of special interest to our profession as custodians of the public health are the questions, What can be done by our railroad companies, not only for the health of their employees, but to secure that their buildings and rolling-stock shall be kept in a thoroughly sanitary condition? and then, What are they doing?

For some time past the Missouri Pacific Railway System has made provision for the efficient and skillful treatment of em-

ployees, who are injured or become sick in its service, by the establishment and maintenance of a large hospital well situated and with abundant room, and with the greatest facilities for giving those who are entitled to it the very best care that is possible.

Similar arrangements have been made by the Wabash System, although that organization has not established a large hospital here. The surgeons of that company have formed a medical society and hold regular meetings, at which papers are read and discussed on such topics as are of special interest to them.

Another step has just been taken by the Missouri Pacific System. A circular has just been issued by Vice-President Hoxie in which is expressed the desire of the managers to place the property of the companies comprised in this system in good sanitary condition, and attention is called at the same time to the importance of such measures to the welfare and prosperity of the employees. The managers express their intention of hearty co-operation with all State and local boards of health with which they may come in contact, and enjoin similar hearty co-operation upon all concerned.

Dr. W. B. Outten, chief surgeon, is placed in charge of all matters pertaining to the sanitary interests of the roads, and all officers and employees are instructed to carry out any rules and directions that may be issued by him. Sanitarians in the East and West will await with interest the publication of Dr. Outten's rules and directions, as the subject of railway sanitation is almost a new one, and the chief surgeon of a system that operates over six thousand miles of track through such a country as that in which these roads lie has an opportunity and a responsibility such as fall to but few men.

Another matter of considerable local sanitary interest is attracting more or less attention in the papers now. For some years the citizens of all other leading cities of our country have been more or less effectively protected from the dangers attendant upon the use of diseased or tainted meats by systems of meat inspection which, in so far as they were faithfully administered, rendered it impracticable, or at least financially dangerous, to offer spoiled meats for sale for human food. Strange as it may seem, the city of St. Louis has had no such system of inspection, and, as a result, it has come to be the fact, as one of the daily papers said, that "St. Louis is the great dumping-ground for all the diseased and damaged meat raised in the West." Last winter an ordinance was passed and an appropriation was made by which a very rigid inspection was established and enforced to the great advantage of the citizens and to that of honest dealers as well, but to the cost and extreme discomfiture of those who had been wont to make money from the poor by selling them diseased or tainted meats. The provision for this, however, was only limited, and when the time came for making a new appropriation so that the same protection might be continued, to their shame be it said, a sufficient number of the House of Delegates were found to cast their votes against the appropriation to defeat it, and, consequently, during the summer weather we are without the needed protection, and unscrupulous butchers and dealers know that our city makes no provision for the protection of its citizens in this regard.

Of course, this danger is one to which the poor are in a peculiar degree exposed. The wealthier citizens purchase costlier meats from dealers who can not afford to risk their reputation by selling bad meat, while the poorer classes buy from those who have little or nothing at stake, and who too often care for naught except to make what gain they may, even at the peril of health or life to the unsuspecting victim. A bill has now passed the Council, and will come before the House of Delegates this week, which makes provision for the renewal of efficient meat inspection.

A good deal of time has been taken up at the meetings of the city Board of Health for some weeks past in considering the subject of closing wells. An ordinance was approved March 25th last, to which I have referred in a former letter, which made provision for the closing of wells that should be found on examination to contain more than six grains of chlorine to the gallon of water. The wells of the city are divided into two classes, viz., those which are in the public streets or sidewalks, and those on private premises. The first class, as a rule, are situated at street corners, and have been sunk by the owners or lessees of saloons or groceries where beer and liquors are sold, for the purpose of attracting custom from teamsters and others who, while securing a free drink for their horses, will step inside and spend five or ten cents for a drink of what may be a little more dangerous in its effects than the polluted water of the wells. Many of these wells were resorted to by neighboring families because the water was clear and cool.

By the ordinance referred to, all wells located in the public streets which should be found to contain six or more grains of chlorine to the gallon were abolished, and, on a certificate to that effect from the Board of Health, it was made the duty of the Street Commissioner to cause them to be filled at the public expense. At a meeting of the Disbursing Committee of the Sanitary Aid Association this week it was reported that, of one hundred and sixty-one wells on public streets which had been condemned, one hundred and fifty-two had been filled. There was a good deal of opposition to the enforcement of this section of the ordinance on the part of the saloon-men, who felt that the closing of their pumps would seriously interfere with their business. Besides, it was argued that it would cause much suffering to animals. One man was very anxious to be allowed to retain his well, with the stipulation that the handle should be removed from the pump and be kept within the saloon, and only be taken out to pump water for horses and stock; in no case to pump water for cooking or drinking by human beings. The Board of Health could see no way to insure its really being used only for cattle, and declined to make any such modification of the order. A case was made and carried to the Supreme Court, which last week rendered a decision sustaining the ordinance and the action of the Board of Health in enforcing it.

The action in regard to the wells on private property is by no means so simple as that in regard to those on the public streets. There are several complications which do not arise in dealing with the water question in Eastern cities. I shall speak of these directly. The ordinance declares all wells located on lots of land fronting on streets, avenues, or alleys, in which the public water-pipe is laid, to be nuisances, *except those which are used exclusively for manufacturing or stable purposes or for watering stock*, or which may be proved, to the satisfaction of the Board of Health, to contain pure water. [Italics mine.] "Any water in wells which shall contain six grains or more of chlorine to a gallon of water shall be deemed to be impure."

One of the first cases which came up before the Board of Health under the section relating to wells on private property was that of a woman who used the water for washing and rinsing clothes. The question at once arose whether such a well was to be excepted from condemnation under the plea that this was to be considered as using the water for manufacturing purposes.

After some discussion, inasmuch as the board were informed that a case had been made up so as to secure a ruling of the Supreme Court as to the whole scope of the law, it was resolved to hear the statements of the various well-owners as to

the use made of the water, and to delay making any final order until the decision of the Supreme Court should be rendered. It seems now that a good deal of time has been lost, as the case that was carried up and the decision of the Court consider only the wells in public streets.

Of course, in dealing with these cases, the Board of Health has encountered the usual prejudice against innovation which is always met with. There has been the usual number of old residents who "have drunk the water from that well for thirty years, and there has never been a case of sickness in the house the whole time." There have been parents whose sick children have been refreshed when fevered by the cool water from that well, and have got well, and who, therefore, can not be convinced that the water is unwholesome for well people.

There have been people who have lived in the same locality, and have drunk water from the same well during two cholera seasons, and who therefore refuse to take alarm at the statement that the water contains from twelve to twenty grains of chlorine to the gallon. All these cases are only repetitions of the experiences which occur wherever well-filling is taken up as a sanitary precaution.

But two difficulties exist here which, I think, are somewhat peculiar. First, as everybody knows who has ever visited St. Louis, our water is by no means clear. At its best it holds in suspension a sufficient quantity of fine impalpable matter, of a sort of yellow-ochre color, which characterizes the water of the Missouri River, from the point where the Yellowstone River empties into it, to give it the appearance of lemonade; at other times it contains enough earth to give it the color of *café au lait*. On allowing it to stand for some hours, all, or nearly all, of this solid matter will settle, and clear water can be obtained for washing and rinsing clothes. (For drinking purposes most people prefer it "in its rich natural state.") As a matter of fact, however, most of those who take in washing, and are dependent upon their laundry-work for their livelihood, have no facilities for settling the river water, though a good many of them have wells from which they have drawn water for rinsing. It certainly would be a hardship to deprive such people of the opportunity so to use the water, and yet in nine cases out of ten where they use the water for this they will also use it for drinking, as it is so much cooler than the hydrant water.

Another difficulty that has been encountered is the fact that, especially in German neighborhoods, there is a prevalent opinion that salting a well will purify the water and make it wholesome, as well as keep it free from various bugs. Therefore, in a good many cases, it has proved that wells which contained a very large amount of chlorine, and, consequently, were supposed to be badly polluted by sewage, really owed the chlorine to salt that had been thrown in by the owners for the purpose of preserving the water from contamination.

LETTER FROM WASHINGTON.

The District Medical Society.—The City's Water-Supply.—The International Medical Congress.—The Hospitals.—Political Appointments.

Washington, *July 12, 1885.*

There has been very little of general interest here since the adjournment of Congress, so far as medical matters are concerned.

The District Medical Society adjourned for the summer last Wednesday. The meetings have been well attended through the year, and interest has been maintained far into the hot term by the discussions on Asiatic cholera and the water-supply of the city. The water-supply question is not yet settled, and there has seemed to be a disposition to make it rather a political than a scientific matter, owing to the apparent criticism of the authorities involved in the discussion. Some points were settled: First, that there was a waste from the canal into the source of the conduit at the river, and, second, that the drainage-basin into the reservoir had included farmers' outhouses, privies, and pig-pen refuse. All this has been corrected, and there is now a sentiment of relief. As usual, those responsible for this not very cheerful state of affairs at first denied the existence of the evils as alleged, and later on abused those engaged in the discussion of them. The water-supply is still inadequate, and a new conduit and an additional reservoir are being constructed. This will furnish an abundance of water for a great many years to come. It is stated that a sewer-pipe from the hospital on the Soldiers' Home reservation passes directly under the new reservoir, and much apprehension is felt by those who know how easy it is for a sewer-pipe to become loose at its connections from the escape of gases and fluid through the cement. This prospective evil admits of a practical remedy by changing the direction of the sewer.

Before adjournment the society re-elected its former officers, Dr. W. W. Johnston, president, and Dr. Thomas McArdle, secretary. Those gentlemen who were originally appointed on the International Medical Congress, and retained by the new committee, have resigned. There was no local grievance.

Dr. J. F. Hartigan, of this city, now in London, is expected to return on the Germanic, which will sail about the 27th of August. The doctor has been hard at work, and has an appointment every day at the Soho Square Hospital and at the East London Children's Hospital.

The rage for incrimination and investigation reached Washington some time since, but seems to have about expended itself. The Children's Hospital imbroglio, that at the Columbia Hospital, and the Wales Court-Martial are the principal topics of medical gossip. In the former case one gentleman, long connected with the hospital, has resigned; at the Columbia Hospital, Dr. Murphy, the physician in charge, has been exonerated.

Dr. R. S. L. Walsh has resigned from the consulting board of the Providence Hospital, and has accepted a position as one of the attending physicians to the Garfield Hospital.

The scramble that took place between the hospitals last year for the appropriation of fifteen thousand dollars, set apart by Congress for hospital purposes, has been happily avoided this year by the appropriation of a specific sum for each.

Dr. T. I. Chew has been appointed physician to the almshouse hospital, vice Dr. T. P. C. Hazen, resigned.

With the coming in of the new administration a race began for the position of health officer of the district, now held by Dr. Smith Townshend. As the present commissioners were decidedly friendly to Dr. Townshend, and as he has had the support of his brother, a member of Congress from Illinois, the various applicants have not up to this time received much encouragement. With the forthcoming change in commissioners it is said a change will be made.

The Board of Pension Examiners has been reorganized to correspond to the views of the politicians by removing Dr. Robert Reyburn. The dissatisfaction at the new arrangement has been so great that two boards have been formed. It is sincerely to be hoped that America may be enlightened and patriotic enough some day to allow honest and efficient medical officers to remain without reference to changes of the administration. If the incumbent is unfitted or unworthy, that would be abundant reason for making a change. Such a reason would not be a political one, but the spoils system, with its outrageous abuses, seems now, as in the past, to be the most tenderly cherished tenet of political faith.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & Co. Edited by FRANK P. FOSTER, M. D.
NEW YORK, SATURDAY, JULY 18, 1885.

THE INTERNATIONAL MEDICAL CONGRESS.

IT was with expressions of anything but hopefulness that we wrote last week of the prospects of the Congress, and we were particularly emphatic in the view that we had insisted upon from the outset, that the entire responsibility for the threatened disaster rested upon the American Medical Association, and not upon its new committee. For a time it seemed as if we were almost alone in the advocacy of this view, but since our last issue was published several things have happened which we interpret as going to show that the responsibility of the American Medical Association is getting to be more and more recognized.

The comments of some of our contemporaries are indicative that they at least are beginning to recognize it, and it is specially noteworthy that the "Medical Bulletin," edited by Dr. Shoemaker, takes considerable pains to show that the committee acted under such instructions that it could not do otherwise than as it did. A most telling piece of testimony in the same direction comes to us in the shape of a letter from Dr. Howard, of Baltimore, which we publish elsewhere in this issue. Explaining why he declined to sign the Baltimore resolution, Dr. Howard puts himself squarely in accord with its signers on the real issue, and explicitly states that he concurs with the Boston resolution, which expressly fixes the responsibility upon the association. It is quite possible that there are others who are perfectly willing to express themselves to this effect, but hesitate to attach their names to anything which may seem like a reflection upon the members of the committee as individuals.

If the association can be made to feel that its action in this matter meets with very general condemnation, there is some hope of its being rescinded in St. Louis next year. If the *status quo* should then be restored, there would still be more than a year in which to prepare for the Congress, and the gentlemen whose further services in its organization have been lost for the time being, in consequence of their having resigned from the committee in disgust, might perhaps be induced to reconsider their determination. It seems now, therefore, that a break may be made in the impenetrable hopelessness of a week ago. But the only way to bring the American Medical Association to its senses is for those of the committee's nominees who have the success of the Congress more at heart than their own tenure of office to continue the good work which has been begun in Philadelphia, Boston, Baltimore, and Washington. These cities happen to be situated in the East, but it is assuredly by no sectional feeling that they have been led, and we think our friends in other quarters of the country make a great mistake if they so interpret the action taken. It has unquestionably become the duty of every well-wisher of the Congress, no matter where he may live, to decline any participation in the emasculated affair which its present organization must necessarily lead to. The impression thus made upon the American Medical Association, together with the unusual care which we hope to see taken in the choice of delegates to its next meeting, may result in the regeneration of that body. This is a matter of even greater importance than the success of the International Medical Congress.

BROOKLYN AND THE INTERNATIONAL MEDICAL CONGRESS.

WE have heretofore given the new committee on the International Medical Congress the credit of having done as good work as seemed to be possible under the stringent restrictions imposed upon it by the New Orleans meeting. Our attention has lately been called to the fact of the very few appointments that fell to the city of Brooklyn—only three in number, while Philadelphia has forty-seven, Boston thirty, Baltimore twenty, and Washington (exclusive of army and navy surgeons) fourteen. In view of the stress that the New Orleans meeting laid on the principle of geographical representation, and bearing in mind that Brooklyn has a population of nearly three quarters of a million—larger, therefore, than that of either of the other cities mentioned, except Philadelphia—it is difficult to avoid the thought that the committee lost sight of the geographical principle in this particular instance. The principle is one which we consider it absurd to proceed upon in such a matter, and we should favor the best possible list of officers, even if every one of them lived in an obscure village; but, if it was to be carried out, it should have been done equably. Especially should such a glaring exception not have been made with regard to a city where so much is done to advance medicine as in Brooklyn. To be sure, the three appointees from that city, Dr. Hutchison, Dr. Squibb, and Dr. Raymond, are quite capable of making an excellent showing for Brooklyn, in case they attend the Congress, but they might appropriately have been reenforced by such men as Armor, Bell, Butler, Byrne, Fowler, French, Gray, Hutchins, Jewett, Mathewson, Pilcher, Rockwell, Segur, Sherwell, Skene, Speir, Thayer, Westbrook, and Wight—men whose names are known wherever current medical literature is read, and who are recognized leaders in the several branches of medicine to which they have devoted themselves.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 14, 1885:

DISEASES.	Week ending July 7.		Week ending July 14.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	1	0
Typhoid fever	13	4	9	2
Scarlet fever	35	5	31	9
Cerebro-spinal meningitis	4	4	4	3
Measles	56	12	55	10
Diphtheria	41	21	55	24
Small-pox	3	0	2	1

Small-pox.—A ship which arrived at this port last week from Liverpool had lost two of her crew with small-pox during the voyage. The vessel was quarantined and fumigated. Press dispatches allude to an epidemic near Creston in Iowa. It is stated that during the three weeks ending on Monday, the 13th inst., thirty-two deaths occurred from the disease in Montreal, fifteen of which took place during the last week of the three, and that six new cases were reported on the 13th. As will be seen by the report of infectious diseases, five cases were discovered in New York during the fortnight ending on Tuesday, one of which proved fatal.

New York State Medical Association, Fifth District Branch.—The first *annual* meeting of the Fifth District Branch will be held in Brooklyn, on Tuesday, October 13, 1885. There will be a morning and afternoon session. All fellows desiring to contribute to the meeting, either by reading papers, notes, or communications, or by exhibiting specimens, are respectfully invited to notify the secretary to that effect at their earliest convenience.

J. C. Hutchison, M. D., *President.*
E. H. Squibb, M. D., *Secretary*, 36 Doughty Street, Brooklyn.

The International Medical Congress and the Medical Profession of Washington.—At a meeting of medical gentlemen held in Washington, D. C., July 11, 1885, the following preamble and resolution were adopted:

Whereas, Certain changes have been made in the constitution and organization of the Ninth International Medical Congress which seem to us unwise, injurious, calculated to bring the profession into disrepute, and to endanger the success of the Congress, therefore

Resolved, That we, the undersigned, decline to hold any position under the said Congress as now organized.

Joseph Taber Johnson, M. D.	S. C. Busey, M. D.
W. W. Johnston, M. D.	H. C. Yarrow, M. D.
Swan M. Burnett, M. D.	A. F. A. King, M. D.
B. F. Pope, M. D., U. S. Army.	Frank Baker, M. D.
E. Carroll Morgan, M. D.	D. Webster Prentiss, M. D.
J. Ford Thompson, M. D.	S. O. Richey, M. D.

D. L. Huntington, M. D., U. S. Army.

The International Medical Congress and the Council of the New York State Medical Association.—The following resolution, recently adopted, reached us too late for insertion in last week's issue:

Resolved, That the Council of the New York State Medical Association respectfully recommend to the Committee of Arrangements for the International Medical Congress the following modification of the rule by which the American membership of the Congress is to be constituted, to wit: That the American membership of the Congress be constituted of delegates who shall be entitled to participate in the business and scientific proceedings, and of members who shall be entitled to participate only in the scientific proceedings of the Congress; that the delegates may be appointed by the American Medical Association and by State and local organizations in affiliation therewith in the proportion of one delegate for every ten or fraction of ten members of the organizations thus represented; that members of the regular medical profession of the United States may become members of the Congress by registering their names as such and by taking out tickets of admission.

The University of Vermont.—It gives us pleasure to insert the following deserved tribute to Dr. Wright:

"The Medical Faculty of the University of Vermont, having been unable to retain permanently the services of Professor J. W. Wright, of New York, as professor of clinical surgery, beg leave, in accepting his declination of the position, to extend to him, both personally and officially, their grateful appreciation of the eminent service he has already rendered the University of Vermont by his course of Lectures on Surgery, just concluded.

"As a skillful operator and a scholarly lecturer, both didactic and clinical, Professor Wright has given universal satisfaction. In leaving the Medical Department of the University of Vermont, Dr. Wright carries with him the best wishes of the Medical Faculty and of the corporate authorities of the University."

M. H. Buckham, *President, University of Vermont.*

[Signed.] A. F. A. King, A. P. Grinnell, R. A. Witthaus, J. Henry Jackson, Henry D. Holton, } *Medical Faculty.*

A New Hospital, endowed by the late Mr. Robert A. Packer and named after him, was opened at Sayre, Pa., on Monday of this week. The building was formerly Mr. Packer's residence.

The late M. Gueneau de Mussy.—According to the "Union médicale," a subscription has been started to obtain funds for a bust of the late M. Noël Guéneau de Mussy, to be placed in the Hôtel-Dieu.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 4, 1885, to July 11, 1885:*

Havard, Valery, Captain and Assistant Surgeon. Assigned to duty at Fort Wadsworth, New York Harbor. S. O. 140, Department of the East, July 2, 1885.

Wyeth, M. C., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Wayne, Michigan. S. O. 140, Department of the East, July 2, 1885.

Powell, Junius L., Captain and Assistant Surgeon. Ordered from Department of the East to Department of the Missouri. S. O. 155, A. G. O., July 9, 1885.

Birmingham, Henry P., First Lieutenant and Assistant Surgeon. Ordered from Department of the Missouri to Department of the East. S. O. 155, A. G. O., July 9, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the week ending July 11, 1885.*

Byrnes, J. C., Passed Assistant Surgeon. Detached from the Powhatan for duty at Navy-Yard, Norfolk, Va.

Cordeiro, F. J. B., Assistant Surgeon. To the Powhatan as relief of Passed Assistant Surgeon Byrnes.

Curtis, L. W., Assistant Surgeon. To Philadelphia for examination preliminary to promotion.

Drennan, M. C., Surgeon. Placed on waiting orders.

Fitzsimmons, P., Surgeon. Duty on Receiving Ship Franklin, Norfolk Navy-Yard, continued until July 1, 1886.

Society Meetings for the Coming Week:

Monday, *July 20th:* Chicago Medical Society; Hartford, Conn., City Medical Association.

Tuesday, *July 21st:* New York Academy of Medicine (Section in Theory and Practice of Medicine); Medical Societies of the Counties of Kings and Otsego (Cooperstown), N. Y.; Ogdensburg, N. Y., Medical Association.

Thursday, *July 23d:* New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); New York Orthopædic Society.

Letters to the Editor.

THE RESPONSIBILITY FOR THE INTERNATIONAL MEDICAL CONGRESS MUDDLE.

BALTIMORE, *July 13, 1885.*

To the Editor of the New York Medical Journal:

SIR: I ask leave to say that I declined signing the resolutions in regard to the International Medical Congress that were forwarded from this city, and published in your journal of the 11th nst. (page 45), because they place the blame for the lamentable state of affairs entirely on the action of the new committee at Chicago, while, as it seems to me, that committee acted simply in accordance with the stringent restrictions imposed upon it by the unwise and revolutionary conduct of the American Medical Association at New Orleans in nullifying the action of the first committee, and thus opening the Pandora's box of the countless evils now agitating the American medical profession.

The resolutions passed at the meeting of the medical men of *Boston*, and published on the same page of your journal, meet with my cordial concurrence.

With great respect,

W. T. HOWARD.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of June 4, 1885.

The President, Dr. A. JACOBI, in the Chair.

Contagious Ophthalmia in some of the Orphan Asylums and Residential Schools of New York City.—Dr. RICHARD H. DERBY, the author of the paper, said it appealed to the hearer on the threefold ground of philanthropy, medicine, and social science. He referred to the report made to the County Medical Society in 1884 concerning the condition of the eyes of the inmates of three institutions in this city, and stated that since then twenty-four other institutions had been visited, containing in all 7,440 inmates. After describing the appearances of the eyes of one suffering from contagious ophthalmia, Dr. Derby said that in the first institution visited 24·5 per cent. of all the inmates had contagious conjunctivitis; in the second, 488 out of 1,586; in the third, 111 out of 782; in the fourth, 93 out of 188. The number of cases in this institution had decreased since his first visit, after which each of the inmates had been given his own towel and brush, etc., and the general hygienic state had been improved. The proportion of cases in several other institutions was then mentioned.

It was not the object of the paper to consider in detail the various conditions which led to the development of contagious eye diseases in the asylums visited. The part played by imperfect quarantine, bad lavatories, overcrowding, bad hygiene—all these had been discussed elsewhere. His purpose would have been attained if he drew attention to the fact that in the asylums of our cities, where children in large numbers were housed, being taken from unhealthy homes, there existed to an alarming extent a disease fraught with danger to the eyes of all assembled there. It would be noticed that in the institutions visited the larger number of cases of contagious ophthalmia existed where the inmates used the towels indiscriminately, washed in the same basin or trough, and slept together, and also where there was general bad hygiene. The disease might be present without attracting the attention of the attendants. In too many instances it went on insidiously, undermining the health of the eyes, until finally an acute attack took place, and gave rise to an epidemic of contagious ophthalmia. We had just seen that of the 7,440 inmates of institutions visited, 1,428, or 19·19 per cent., had contagious conjunctivitis, or nearly one in every five. Besides, in several of the institutions it was the custom to send the worst patients to their homes, where they might seek treatment outside, thus rendering probable the further spread of the disease among the neighbors. The parents of such children were not properly situated for carrying out effectual treatment, and were unable to care for them in a suitable manner. In many cases it was to the advantage of the institution to receive as many inmates as possible, and thus overcrowding was encouraged.

The Board of Health should be notified of every case of contagious ophthalmia in any of the institutions, and accommodations should be provided for isolating the patient until he was no longer capable of communicating the disease. There were enough cases of contagious ophthalmia in the institutions at present to fill a hospital devoted to their isolation and treatment. It behooved the members of the Academy of Medicine to make emphatic protest against the continuance of the present state of things.

Dr. H. KNAPP said the statements of the speaker ought in no way be underrated. He had been connected with a number of institutions as ophthalmic surgeon, and knew that in a number of them, and perhaps at certain periods in all of them, contagious ophthalmia existed. Sometimes the spread of the disease had been so great that the authorities of the institutions were forced to close them and to farm the inmates out. But he could, on the other hand, state that in many of the institutions the greatest care was taken to stamp out the disease. He mentioned the Catholic Protectory in particular, where, when an epidemic broke out, they called physicians and sought in every way possible to stamp out the disease, and the spread of the blennorrhœa was largely controlled. But, where an institution was once invaded, a number of cases were liable to continue for a long time. Two institutions never admitted a patient with eye disease until they had received a certificate from him that the disease was not contagious; the patients were sent to an ophthalmic institution until they were cured of the contagious affection. These institutions were remarkably free from eye diseases. He thought the suggestion of the author of the paper regarding competent inspection of all cases of eye disease in these institutions a good one, and believed that, if a physician were engaged to make a monthly report of the condition of the eyes of the inmates, at least large epidemics would be avoided. In this seemed to be the nucleus of the paper, and he knew of nothing more philanthropic which could engage attention.

Dr. D. B. ST. JOHN ROOSA said that that afternoon, at the request of the physician of an asylum, he had examined the eyes of 242 inmates and found 67 cases of conjunctivitis. These children were under as good care as they could have, thanks to the labors of the author of the paper, except that there was not isolation. But the authorities of the institutions were not altogether to be blamed for the existing condition of things. If there was any power in the Board of Health to correct such matters, it was its urgent duty to do so. Children suffering from eye disease were often forced upon the managers of asylums in a manner that they could scarcely resist. The writer had observed with great propriety how very wrong it was to send these children back to their already overworked parents or

guardians with the hope that they might remedy the matter. The remedy was easy. The tax-payers should pay for a hospital where patients suffering from contagious ophthalmia could be sent and retained until cured and then be returned to the institution without danger of spreading the disease. The subject was one deserving the consideration of political philanthropists, and the Board of Health should insist upon the erection of a suitable hospital, and it would be found, as it had always been found in like cases, that the people of New York were ready to give their money for deserving charities.

Dr. Oakman, of Nyack, said that during the winter the authorities of the institution at that place, where about one hundred inmates were admitted, failed to isolate certain cases of eye trouble which he advised should be done, they maintaining that the disease was the result of cold. In order to keep the inmates warm they were huddled together in an ill-ventilated room, and the result was that in the spring there were forty-four cases of catarrhal trouble of the eyes, seven of acute granular trachoma, and one of purulent ophthalmia.

Dr. C. R. Agnew said his interest in this matter had begun nearly thirty years before, when he saw a great many cases of contagious conjunctivitis during a famine in Ireland, and to this day that disease was quite common there, having started from overcrowding in poor-houses and other public institutions. He referred to a school in this city where contagious ophthalmia was communicated to eight tenths of the inmates, probably largely by the habit of washing together in one trough. They were also insufficiently fed, and several slept in the same bed. A remarkable change for the better had taken place when they were placed in tents and given four hundred quarts of milk a day instead of fifteen quarts. Dr. Agnew had great faith in the effect of agitation in bringing about a reform of abuses. It was not always wise to seek legislation, but in this case he thought something should be done by way of legislation. It should be required of those who were about to found an institution to lodge a certificate showing that they had made proper provision for air-space, shelter, food, and medical attendance for a certain number of inmates, and it should be made impossible for such institutions to receive more persons than the number for which they had the lawful accommodations. This was quite as possible as to regulate the number of passengers which a ship of given measurements should carry. The large majority of children in these institutions having chronic conjunctivitis never recovered, and they went to make up that large body of drifting, despairing creatures who infested our towns and cities.

Mr. Gerry, of the Society for the Prevention of Cruelty to Children, explained the manner in which commitments were made to these institutions, and said that, with certain exceptions, many of the institutions where the children were sent were entirely under the control of persons who had no knowledge of medicine, or even of nursing, and there was no provision in the law which required them even to seek the advice of a physician. Unless they were required to submit to the judgment either of a medical board or of some competent medical man, they would always have in their institutions cases of contagious ophthalmia. He was entirely in accord with the views expressed by Dr. Agnew, and thought that something should be done by law to provide for an oversight of these institutions by medical authorities. He thought, so far as an ophthalmic hospital was concerned, that the remedy was simple. Let the State pay liberally for the care of such cases, and they would find proper isolation and treatment. The difficulty with regard to the Board of Health was that it was a quasi-political body; it already had its hands too full of work, it had not the means, and, when money was asked for, it was put off with the reply that it was always calling for money. One objection to an ophthalmic hospital was that the people would feel that as soon as a child was sent there its condition was hopeless.

Mr. Milhau, of the State Board of Charities, explained the duties of that board with regard to recommending the establishment of institutions organized by private individuals, and said that, while such institutions usually started under favorable conditions, it was only a short time before they began to receive children faster than they were able to provide accommodations for them. Then there were institutions which were considered absolutely safe, being under the highest medical supervision, and yet ophthalmia would break out.

The President said it was apparent, from the remarks which had been made, that it was almost impossible to keep contagious ophthalmia out of institutions. The same was true of every other contagious disease; they all made their appearance at times in institutions crowded with inmates. All of these institutions were meant to do good, and all did at the same time a great deal of harm. Where there were many children there were many opportunities for danger. Measles usually was a very mild disease, but when it broke out in public institutions it became very dangerous, and the same was true of all contagious diseases; they were more fatal when present among the inmates of crowded institutions. In an eye hospital a mild case of ophthalmia would become a very severe one, and he was not sure that much good would come from a hospital devoted specially to those cases. The question would finally arise, whether public institutions where large numbers of persons were congregated should be allowed to exist at all. If the children gathered in those which at present existed were farmed out it would be much better for them; there would be fewer cases of ophthalmia and of blindness.

Dr. W. F. Mittendorf said it was difficult to make the public understand two points with regard to contagious ophthalmia: first, its great danger to the eyes, and, second, the length of time it required to cure it. He had had much to do with asylums, and he thought, with the president, that the crowding of children together in institutions was a great source of danger. In certain institutions where the inmates lived in cottages he had seen little of eye disease. Another point which was too often overlooked was the extreme contagiousness of the affection. It was because of its great liability to spread that the eye institutions in the city did not like to accept cases of contagious ophthalmia. The suggestion of the president was, it seemed to him, the best that could be adopted—namely, to put as few inmates into one building as possible.

Dr. Agnew offered the following resolutions, which were unanimously adopted:

Resolved, That it is necessary and expedient that steps be taken to prevent the occurrence of communicable eye diseases in the schools and asylums of New York and vicinity.

Resolved, That the Council of the Academy be requested to take the matter of the paper into its immediate consideration, to obtain the co-operation of the writer of the paper, of the Society for the Prevention of Cruelty to Children, of the State Board of Charities, of the State Charities Aid Association, and others interested in the subject, for the purpose of lessening the prevalence of communicable eye disease.

Dr. Roosa wished to say one word more in favor of an ophthalmic hospital. It had been shown in the discussion that contagious ophthalmia, although easily spread, was also amenable to treatment, and, so long as institutions existed where it was liable to occur, there should be a hospital where patients could be sent for isolation and treatment. Of course, this would not be necessary when things were in New York as they were in Utopia, and children were all farmed out instead of being put into institutions.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of June 4, 1885.

(*Concluded from page 55.*)

The Surgical Treatment of Infants.—Dr. WILLARD's paper was concluded as follows:

Congenital hydrocele rarely requires much surgical interference beyond an evaporating lotion of chloride of ammonium or alcohol, as a few weeks will often close the canal, if hernia does not co-exist—a fact which can be determined by non-translucency and capability of reduction. Should the connection with the peritonæum fail to close, puncture, with the application of a truss, will usually complete the cure. A hydrocele with closed canal is better treated by tapping and injection than by seton. The diagnosis between *encysted hydrocele* of the cord, *hernia*, and *undescended testicle* is sometimes difficult, but, if the surgeon remembers that the former is simply a cyst in some unobliterated portion of the peritoneal coat of the cord, that its rounded shape can be detected if it is pulled well down into the scrotum, that it is usually translucent, that the impulse is not so decided as in the case of hernia, that it returns to the abdomen only by being pressed upward and not with a slip and gurgle, he will rarely be led astray. A hernia may co-exist with either of the above-mentioned conditions, but, if non-adherent, careful isolation will settle the diagnosis. Should the hernia become strangulated or the non-descended testicle become inflamed and infiltrated, the most careful examination will be necessary. In retained testicle, its absence from the scrotum will be the first point in arriving at a decision, but even in such a condition the organ might be within the abdomen and an encysted hydrocele present, or the testis might, as has recently fallen under my notice, slip into the tissues of the perinæum and be exceedingly difficult to discover. In the case just mentioned it sometimes requires numerous manipulations to cause the missing organ to return to its place in the pouch. Should hernia and retained testicle both exist, a double purpose can be gained by drawing the latter down, and pushing the former up and then applying a truss. The successful retention of the organ within the scrotum is a matter of great difficulty, and removal is scarcely justifiable in young persons unless pain or inflammation ensues. Extirpation, if required in later youth, will probably not interfere with the procreative power of the individual, since one gland will supply all requisite material, and the affected one is practically useless from atrophy, even if it is not devoid of tubular structure. Traction is of little service, as manipulation tends to increase the sensitiveness of the organ.

Simple *umbilical* and *inguinal hernia* should receive early attention, as, contrary to the rule in adults, a cure can often be effected during the first year of life by the persistent use of a truss. In young infants I prefer the hard-rubber variety as more cleanly. The instrument should be applied during the first few weeks of life and continued for one or more years. The treatment of strangulated hernia does not differ from that in the adult, but, in obstruction of the bowels, *intussusception* is so commonly the cause of the blockade that, unless violent peritonitis is present, laparotomy, with careful search for the invagination, offers the best hope of relief, and, I am glad to say, is rapidly growing in favor.

Meningocele, *encephalocele*, and *spina bifida* are complaints that will early require the surgeon's attention, or at least his expression of opinion and his prognosis. If attached by means of a narrow pedicle, constriction with an elastic band is feasible, but, unfortunately, this pedicle is but seldom found. Injection of iodine, following tapping, is rarely successful, yet is worthy of trial in so hopeless a task. In a large hydrorrhachis of the lumbar region, lately under my care, which resisted pressure, tapping, injection, and constriction, I was strongly inclined to excise the thin sac and attempt a plastic operation by drawing in toward the median line two flaps of skin from the lumbar region, leaving the vacancies to granulate. Soon after a consultation, in which I was dissuaded from my attempt, the tumor ruptured spontaneously and death occurred in two days, although frequent tappings had never produced any nervous symptoms. I had then never seen a record of such a plan of procedure, but only last week I noticed in the "Journal of the American Medical Association," vol. iv, No. 17, p. 466, that Mr. Robson had performed this operation with successful results in two out of four cases. Strict antisepsis was enforced.

Cephalhæmatomata are usually easily distinguished from encephalocele or meningocele, and also from the simpler tumor, caput succedaneum, the latter being exterior to the periosteum and more doughy. The blood in a cephalhæmatoma is always confined between the pericranium and the bone substance, and increases until the second or third day. The hardened ridge around the border of the tumor may give the sensation of an opening in the bone, but the orifice in meningocele is rarely as large as the base of the swelling mentioned. The peculiar crackling feeling upon pressure at a later period is due to the new bone deposits beneath the periosteum. Absorption so generally takes place in three or four weeks that aspiration or incision is unwise, even though antisepsis be thoroughly practiced, unless in exceptional cases when suppuration is certainly present.

Hare-lip will early require the careful study of the surgeon, situated as it is upon the portion of the body that is most regarded from the cosmetic point of view. Its proper relief therefore becomes not only a matter of surgical skill, but of surgico-artistic skill. The time for the performance of the operation is a point upon which there is a wide diversity of opinion. My rule is to relieve the deformity within three or four days if it interferes with the proper nursing of the child. Practically I must confess, however, that by the end of the operation the milk has left the mother's breast, unless there is some other baby to maintain the flow. My preference is to wait about three months, until a full, vigorous activity of growth and cell action is at work, and before the process of dentition has commenced. This period is selected not only for the reason mentioned, but also because the child can not use its hands so freely as at a late period of infancy, thus avoiding risk of injury. In one patient a year old, diphtheria appeared on the day following operation, and in his convulsions all the pins were twice torn entirely from their fastenings and the fresh wound became implicated. In spite of such complication, an excellent result was obtained by holding the parts in position for days with adhesive plaster cut in the form of a triangle, sufficiently large to cover at its base the area from in front of the ear to the corner of the hyoid bone, with its apex prolonged at the width of the upper lip to meet a similarly shaped piece from the opposite side. These sections were united by a small elastic ring which maintained a constant pull upon the tissues of the cheek and controlled spasmodic muscular action. In fractious children I have now discarded pins and have substituted catgut sutures for the mucous surfaces, which, if of small size and tied in three knots, will remain in position until union occurs. For the skin edges I use carbolized interrupted silk sutures, my reason for stitching the surfaces separately being that there is less linear depression of the cicatrix, and less constriction of tissues is thereby exercised than by pins and the figure-of-eight, while, if each set penetrates half-way through the lip antero-posteriorly, the sphincter is thoroughly controlled. One of the stitches should pierce the coronary arteries. To prevent pouching of the flaps or separation of the deeper parts by oozing, horse-hair drainage

for a few hours answers the best purpose. Additional control of muscles should be given by adhesive plaster prepared as above indicated or by strips, which should not only be applied transversely, but, in order to prevent strain, should commence upon the neck on either side, in front of the sterno-mastoid, near the cornu of the hyoid, and run thence just above the angle of the mouth across the opposite malar to the front of the ear. If these are all put in position while the surgeon pinches the cheeks well together, he will find, upon releasing his grasp, that the minimum of tension is exerted upon the stitches. A still better plan is to have the nurse regulate this muscular action for the first few days by pressure whenever the child cries or eats. Only by securing union by the first intention can we hope to have a narrow cicatrix; hence I do not allow the child to suck, as is the practice with some surgeons, but prefer spoon-feeding, as producing less disturbance. For the same reason, anodynes should be employed to control pain and keep the little one for a few days in a quiescent state. The child should be in the best possible condition physically, as quick union is desirable. To avoid the marginal depression so commonly seen, and which is inevitable if the simple inverted V-incision is used, I never sacrifice any portion of the paring, but, commencing the incision at the apex of the cleft, stop it just before it reaches the border of the lip, thus leaving a base of supply to nourish the flap which remains on either side. These two flaps, when the parts are brought together, project downward and form a fleshy prominence: but, if stitched nicely together, will unite and, from subsequent absorption during the next year, give a slight projection. Even should this be larger than desirable, it is far preferable to the ugly notch which can not be corrected, since a simple scissor-cut will remove all redundancy and give a nearly normal lip. The same rule in regard to utilization of tissue holds good in complicated cases of hare-lip when it becomes necessary to save as much of the alveolus as possible. Broken or cut, it can often be worked to advantage in bridging the chasm or supporting a fallen nasal septum.

If *cleft palate* co-exists with hare-lip, an additional necessity for early treatment is present, since the closure of the lip will tend greatly to lessen the gap in the hard palate. Dentists realize more fully than surgeons how slight is the pressure required to act upon a tooth or upon the alveolar process, but a moment's reflection will convince any practical man that such narrowing can be accomplished even if he has never witnessed it. In these instances, as in hare-lip and many other deformities, neglect is often as much the fault of the physician as of the family. An early operation upon the lip, strong pressure upon the maxillary bones, followed by the use of a Hainsby's compressor, will in a few years bring the cleft so close together that a single operation will unite the edges.

These are the considerations which influence me in advising that, while the lip should be closed early, the cleft-palate operation be deferred until the plan has been tested. Few children from five to ten are tractable enough to endure the pain of a staphylorrhaphy without ether, which is desirable, and I see no particular harm in delaying the procedure until the latter period, save that the unused or malused muscles will require a longer period of education after closure. In a recent staphylorrhaphy upon a boy of sixteen the letters of the alphabet could, however, all be correctly pronounced in three weeks except the *k* and hard-*c* sounds. If a good velum and uvula can be secured by union, the hard palate can be admirably assisted by an obturator. Only last week, by preliminary touching and the use of cocaine, I was able, in a child of five years, to make the parings without pain, and thus avoided anæsthesia until all hæmorrhage had ceased, ether being employed for stitching only.

Tongue-tie is a condition that exists more frequently in imagination than in reality, yet the operation for its relief need be no more than the most trifling nick of the frænum, the finger completing the work. If the organ can be protruded to the red border of the lip, no operation is necessary.

Club-foot is a deformity which is frequently neglected, not alone from the apathy of parents, but, as is shown by the cases which come under my notice, far more frequently from the incomprehensible advice of the family physician, who has counseled that "nothing shall be done for the present." Weeks slip away into months and months into years, during which time one set of muscular fibers and one set of ligaments have become elongated, while the opposite ones are atrophied, condensed, and shortened. Bones, too, have become distorted and wedge-shaped, and the difficulties have, of course, increased fourfold with each advancing year. I have never been able to see any reason why delay should be countenanced a single day after birth, since manipulation and subsequent fixation can easily be accomplished at the first dressing of the child. I know of no words sufficiently strong to characterize such neglect of duty as is seen in numerous instances. Twice in the last three days have I had this matter brought before me by parents who have come to the office and who have given as the reason of their inaction that the physician had directed them to wait. Even before the age for walking, great condensation of tissue will take place and increase of deformity will occur from simple pressure of clothing, but, as soon as the weight of the body is brought to bear upon these misshapen members, the change will be rapid. The secret of the cure of club-foot lies not in operation, but in careful attention to all the means of relief. At the first hour of birth, as I have said, manipulation should be commenced by bringing the foot from the abnormal into a normal position, or as near it as possible, and confining it there by wood, felt, binder's board, or leather splints rightly adapted. At the next visit, leather, gutta-percha, or, preferably, printer's-blanket cinctures, should be laced upon the foot and leg, and connected by an elastic strap. The two-ply printer's blanket, with its rubber face, does not slip, even when applied with only moderate tightness, thus being superior to other materials. Hook-eyelets are easily inserted by any shoemaker, and the lacing need not impede circulation. Manipulation can be practiced twenty times a day without taking off the apparatus, while removal at night gives opportunities for massage, frictions, etc. If co-operation of parents is wanting, plaster of Paris can be employed with excellent advantage for fixation, a gain being effected with each month's renewal of the dressing. Leather, felt, sheet-lead, and silicate of sodium are of use, but do not permit removal for manipulation, and are, therefore, inferior to the bands already mentioned. These bands, which permit of constant elastic traction day and night, are very inexpensive if remnants are bought. Their use puts the successful early treatment of any case of talipes into the hands of the ordinary practitioner for the first few months of life. In cases which are of a severe type, a subsequent operation is usually necessary, but the manipulation which has been practiced up to the time for tenotomy stretches condensed tissues and increases nutrition so that relapse after division of the tendons will not occur, if the same measures are continued subsequently. Failure after tenotomy is nearly always due to the neglect of manipulation. The special form of apparatus is far less important than a strict attention to details. The chief advantage of the shoe which I employ lies in the fact that it permits manipulation and stretching without removal, owing to its flexible sole-shank of upper-leathers, which acts perfectly as a ball-and-socket joint, the force being exerted by an elastic strap operating upon the foot

through a catgut cord passing through an eye attached to the upright. The eye-bearing arm is ordinarily constructed with too little an outward bend. If I can control the patient I rarely operate until I have the tissues thoroughly stretched, but if the foot can not be placed upon its plantar surface at eight or nine months—that is, when the age of walking arrives—tenotomy should be delayed no longer, since each step will increase the deformity. In operating, I divide every tissue that interferes with perfect straightening, whether it is tendinous or fascial. The tendon of the posterior tibial is an exceedingly difficult one to sever in a fat infant with a poorly developed heel. The puncture should be made just below the malleolus, and, having placed the back of a tenotome toward the artery, division can be safely made. Tenotomes, as found in the shops, have too long a cutting surface for infantile work, as the sharp edge will frequently enlarge the external wound unnecessarily. It is my practice to leave the tendo Achillis until the end of the operation, in order to gain its fixation power in the leverage required for stretching the parts into position, a procedure which is best accomplished at the time of operation. The amount of power which should be employed in this process is governed by the degree of resistance and the caution of the surgeon, special care being taken that the force is expended only on the resistant tissues. In the class of cases with which this paper deals—namely, those of young infants—it is scarcely possible that tarsectomy could be called for, although an English surgeon has thus operated upon a sixteen-months-old babe. I now use the gypsum dressing entirely after tenotomy, not only since it is less expensive, but chiefly because it holds the foot and heel in much better position than is possible by any apparatus, and is less liable to produce sloughing, because the pressure is exerted over the entire surface. The instances where plaster produces a slough are always due to faulty application, mainly caused by some indentation produced during the setting process. If the bandages are smoothly and rapidly applied (salt having been added to the water in which they are immersed), the surgeon can, by grasping the knee, hold it steadily in place, while, with the palm of his other hand placed against the plantar surface of the child's foot, complete rectification can be maintained until the plaster hardens without danger of depressing any region of the cast. A dossil of curled hair or cotton placed over the ball of the great toe and the prominence of the cuboid or astragalus, and confined in position by the flannel bandage enveloping the foot, will also assist in averting any harmful pressure.

I can not too strongly emphasize my appreciation of plaster of Paris in the treatment of *fractures* in infants, giving, as it does, a perfectly adaptable material, and yet, when hardened, securing an immobility of the injured part that permits free handling, provided the articulation both above and below the injury is included in the dressing. This is feasible even in fractures near the hip, since the splint can be made to encircle the thorax, and thus prevent the great motion that is always present if only the pelvis is fixed. No risk of injurious swelling need be feared if a flannel bandage or a thin layer of cotton is first applied to the limb. It is better to saw open a dressing at the end of two weeks, and either tighten it or apply a new one. Silicate and other rigid dressings harden so slowly that displacement may occur during the process. The fractures occurring during birth are often overlooked for several days, and the fact that the child moves a particular portion of its body freely is not proof that lesion of bone has not occurred. I have seen several instances of fractured clavicle in which the child indulged in most vigorous movements of the arm. These collar-bone breaks are quite common, either from falling out of bed, from careless handling, or from the playful jerking of other children. The under-waist of an older child, placed in proper position over the sound arm and pinned tightly around the body so as to include the injured member, often keeps in place better in fat babies than a Velpeau bandage, especially if the hand is secured with a loop. Borated cotton should be placed in the axilla.

Green-stick fractures are best treated by etherizing the child and slowly straightening the bone by hand-pressure. Even should complete solution occur, the result will be good. A slight curve can be reduced by a splint and bandage. Separations of epiphyses are practically fractures, and should be treated as such.

Dislocations do not differ from similar injuries in adults, save that they are even more readily replaced by manipulation.

The resultant deformities of *infantile paralysis* are numerous, and are frequently passed over by both physician and parents, under the erroneous impression that nothing can be done for the relief of these poor weakened members. Recognizing that restoration is best accomplished by massage, electricity, etc., and particularly by action, it is my rule never to assist a muscle if it is capable of permitting locomotion, or unless deformity is being produced by non-support. The following are the considerations that determine the necessity for apparatus: If a bone is bending, an articular surface becoming distorted, a ligament yielding, or muscles becoming atrophied from excessive stretching, or if, by applying a support, the child can be made to walk, then I always order an apparatus which shall not take the place of the enfeebled muscles, or put them in splints at rest, but which shall render just enough resistance to enable them by contraction to accomplish the desired purpose. If rigid steel is used, they will soon relinquish their attempts at assertion of power, and enfeeblement will increase. By a judicious adaptation of mechanical appliances, many who are now condemned to chairs and beds can be placed upon their feet. The advisability of tenotomy will depend upon the benefit to be gained by such a procedure. In many cases it will assist greatly in placing limbs in proper position for locomotion, and for this reason its mechanical effect should be thoroughly studied. My observation leads me to believe that it is employed too seldom. The excision and shortening of tendons by suturing is often of advantage. Any irregularity in the length of limbs should be counteracted, lest lateral curvature result.

Nævi, if situated upon exposed portions of the body, must be cured early in life if rapidly increasing in size, and in the majority of cases should be attended to before six months is reached. The question of excision, ligature, subcutaneous ligature, injection, electrolysis, or sun-heat, will depend upon situation, size, etc.

Webbed fingers and *supernumerary toes and fingers* will yield smaller resultant scars if operated on during the first half-year of life.

Wry-neck may follow injury to the spinal accessory nerve during labor, or it may be found as a result of some of the exanthemata. If resistant to local and constitutional remedies, myotomy should be performed at the end of a year.

Spinal caries in young children can be retarded by placing the sufferer upon its back between two sand-bags, while passive motion is employed to develop muscular power. A jacket or cuirass may be added if bone-death is rapid, or if difficulty of retention is experienced. Horizontal extension is rarely necessary. I have occasionally seen *lateral curvature* in weak infants caused by the mother's habit of always holding them in one position, the reversal of which custom has, together with constitutional remedies, completed a cure. It may also be the result of a rhachitic tendency, which will necessitate the appropriate medicinal and hygienic management. Simple posterior

curvature, and also lordosis, are sometimes found, and should be closely watched, as other symptoms of that disease of malnutrition, rickets, may soon present themselves. Dorsal decubitus should be maintained until the proper treatment has had time to strengthen the child. *Rickets*, fortunately, is seen upon this side of the Atlantic far less frequently than on the eastern shores, and, I am thankful to say, is seldom found in Philadelphia even as compared with New York. In fifty thousand cases in our hospitals, I find that fewer than fifty are enumerated under rickets and its results, including knock-knee, bow-legs, etc. Its onset is usually within the first six months of life, but, unfortunately, many cases are not brought to the notice of the surgeon until one or two years have elapsed and great deformity has already resulted. When pronounced, the most rigid care should be taken to prevent the distortions, from which no bone in the body seems exempt. The effects upon the female pelvis are most disastrous, as life is thereby endangered. The recumbent position is the only safe one, and must be maintained until the general remedies have time to act, passive motion meanwhile taking the place of active. The *tibial curves* are the most common of defects. Very slight bowing is sometimes corrected in the growth of the individual, but we have no more right to expect that such a result will spontaneously occur than that a crooked tree will be blown into the upright position by chance winds. The proper means should always be used to compel rectification. If the bones are spongy, much can be expected from manipulation, pressure, and apparatus properly constructed. During the first two years of life we may confidently hope to accomplish a good result by such means, but in later childhood or adult life, if the deflections are great and the bones rigid, and especially if the curve is anterior, but little can be gained by these means, and osteotomy is the more certain and speedy means of relief. The risks of this operation, if done antiseptically, are but very slight, as the case, if sealed, becomes one of simple fracture. Plaster of Paris, again, gives us the best means of fixation after operation, and is very comfortable to the patient.

I approve of instruments in lateral bow-legs, but, when they fail to secure straight limbs in the class of cases above mentioned, I firmly advocate operation. The deformity, if allowed to continue, is not only unsightly, but also interferes greatly with the locomotive powers. It is not true that a bow-legged man is strong. He has, on the contrary, to use his limbs at a disadvantage, and, if he is vigorous, it is in spite of his complaint.

The question of *tracheotomy in young infants*, with whom our present discussion chiefly deals, is one demanding the gravest consideration, whether the dyspnœa originates from diphtheria or from true croup. So fatal are the results that the mortality in babes below the age of six months is placed by some writers as high as ninety-five per cent., and, even taking all under two years, we can not expect to save more than from ten to fifteen per cent. When we consider, however, that some English writers place the mortality of croup without operation at ninety per cent., we can not believe that the operation has increased the number of deaths. Moreover, when cases are taken at the most favorable age and the most favorable conditions, we can scarcely hope to save more than twenty-five per cent. of all patients operated on. I have spoken thus in regard to prognosis since some surgeons absolutely condemn the employment of tracheotomy for these young patients. I can not feel, however, that they are absolutely hopeless, and, if surgery can relieve them from the horrid death by suffocation, we should not hesitate to give them the aid of science, although a true tracheotomy is well-nigh impossible in a young, fat infant, owing to the exceeding shortness of the trachea and the great size of the thyroid body. It is usually best to do an inferior laryngotomy (or crico-thyro-laryngotomy), making the opening through the crico-thyroid membrane, and also through the cricoid if necessary. The risk of hæmorrhage is thereby greatly diminished, since, while the crico-thyroid arteries may be cut, they will be far less troublesome to secure than the vessels about the thyroid body or the middle thyroid artery, which often lies in front of the trachea. Again, the innominate artery may rise high in the neck, or a wound of a vein near the innominate may speedily kill the little one, as has happened in a number of instances, even when the operator has been experienced. The fact that surgeons who have opened the windpipe several hundred times look upon this operation as an exceedingly difficult one is proof that the utmost care is necessary. The danger of wandering from the median line may be partially obviated by having the child's head kept perfectly straight and by placing the body in exact line with the table. The trachea is sometimes missed because it has not been thoroughly cleared of everything before attempting to open it. The puncture should be made firmly but guardedly. The size of an infant's trachea will surprise one who has never studied it. Although I have given large and special study to the anatomy of childhood, both from the cadaver and clinically, my first tracheotomy patient died on the table before I could insert the tube, my error being in trying to push the cannula too far back. Unless the urgency is great, ether should be given in moderate amount and the operation carefully performed. A plunge into the trachea is never good surgery; in infants it would be worse than folly. If a circular piece is taken from the crico-thyroid membrane and the cricoid, and a pilot used, introduction will be rendered more easy. In fat necks, the windpipe may be brought nearer the surface by extending the head far backward and by grasping the tube on either side and dragging it forward. If fixed thus in the median line and retained continuously by an assistant, much time will be gained. In a recent case I found it wiser to go above a large thyroid body, even in a five-year-old child, and insert the cannula in the crico-thyroid space. There was afterward a slight burying of the upper edge of the plate, owing to its high position, but a strip of sheet-lead obviated this difficulty. To arrest the venous hæmorrhage, just before puncture, hot-water sponges answer admirably. After operation, the temperature of the room should be kept above 80°. I have never opened the larynx to remove a foreign body in a very young child, but the universal habit of making the mouth the general receptacle of everything makes the introduction of such substances exceedingly probable at from one to two years.

Foreign bodies in the nose, which can not be seized, if not removed by sternutatories, should always be sought for with the aid of anæsthetics. In the ear the opposite mode holds good, since consciousness of pain will often prevent an unskilled practitioner from doing great injury to the membrana tympani.

Joint diseases are best treated by recumbency, with fixation or extension.

Excisions are rarely performed at this early age, and need not therefore be discussed.

I omit strumous and syphilitic diseases and a score of other conditions, which might well detain us for hours, since time forbids.

I have thus, gentlemen, hastily touched upon only the more frequent of the surgical maladies met with in daily practice among infants. Many of the suggestions may be already familiar to you, but even the brief mention which I have been allowed to bestow upon each subject may possibly have served to revive in your minds old and forgotten experiences, and thus be helpful. You will, at least, see that the field is a wide one, and that results are most encouraging.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of May 19, 1885.

(*Concluded from page 49.*)

The Eradication of Syphilis during the First Stage by Surgical Means.—Dr. A. H. P. Leuf read a paper on this subject. [See page 36.]

Dr. F. N. Otis, of New York, said that the treatment of syphilis was a subject in which he was very much interested, and especially as to the point which was announced for discussion this evening, namely, the eradication by surgical means. It was a subject which had interested the surgical world for a number of years. Auspitz and Kölliker, of Vienna, he believed, were among the first who had claimed success in eradicating syphilis by excision of the initial lesion, and reported a large number of cases—something less than half a hundred. Others had supported the claims of Auspitz by citation of similar success both in this country and abroad, but it was still a mooted question whether or not syphilis could be eradicated by excision of the initial lesion. It was well understood and had been ably expressed by the author of the paper that the invasion of syphilis was a gradual process, that the chancre, or initial lesion, was the first manifestation, and the second observable manifestation was the enlargement of the glands in connection with it, wherever situated. There were, however, a number of points about which mistakes might arise in taking the paper exactly in the terms in which it had been read. For instance, in describing the chancre as an "ulcer" we had to recognize that the chancre was not an ulcer primarily, and was not necessarily an ulcer at all, and that the processes of syphilis were not destructive. There was always destruction in chancroid, and this was one of the differences between chancre and chancroid. Chancre might be acquired without any recognized abrasion or breach of the surface. The virus might enter through a ruptured hair follicle. Syphilis might enter through some unobserved wound, which healed promptly, no destruction taking place, and yet the person would have syphilis just as certainly and as severely as if the introduction of the syphilitic principle was followed by a typical Hunterian chancre. It was not a process of destruction, but of *proliferation*, from the very beginning. Proliferation and aggregation of cells, wherever it commenced, were always its characteristic, whether great or small. Now, excision of these cells had been asserted to relieve the system of danger of syphilis, they being assumed to be the starting-point. It had been demonstrated by histologists beyond cavil that this difficulty, instead of being the result of a general instantaneous infection, always commenced at a given point, and that there was a contagium introduced through a lesion of the skin, or mucous membrane, which traversed the system slowly through the lymphatic spaces and vessels. Having, then, its beginning at a certain point, if it could be determined that it had not gone much farther, we might hope for its eradication by surgical procedure. But the syphilitic principle, so far as we know anything about it, was a cell which possessed the power of motion, the power of traversing tissue, and it had also the power of generating other cells having equally the power of traversing tissues. They were not quiescent, but were always moving to a greater or less extent, and in a short time—a few days or, perhaps, weeks—they would have traveled along the lymphatic vessels and have established local points of proliferation in neighboring lymphatic glands, thus accumulating, so that the glands became emphatically identical with the chancre—the initial lesion of syphilis. They contained the same vitiated cell material. Inoculations with the cell material from these glands would produce syphilis in a healthy person as certainly as with the secretion of the typical chancre. We had, then, these cells traversing lymph-spaces and vessels; and it had been maintained, on examination, that they often clung to the sides of the lymph channels on their passage through them, and in this way often blocked up such channels completely for the time being. It was not unusual to see a line of lymphatic vessels extending from the initial lesion to the glands in the groin distinctly marked by an induration caused by accumulation of newly generated cells, and, if this be the case, it seemed impossible, then, that by excision of the initial lesion alone syphilis could be cured. In order to prevent its passage into the system, we must eradicate every infected cell, not alone the initial lesion, but those which had passed from it into the lymph-spaces, vessels, and glands in connection with it. This, of course, would necessitate an amount of surgical interference which would hardly be justifiable under the circumstances. The facts were, so far as he knew anything about them, that as yet no case had ever been cured by a simple excision of the initial lesion, for the reason that the cells had got beyond the reach of the surgeon's knife before he had ascertained the presence of this accumulation. He had himself excised perhaps twenty or thirty chancres, and carefully kept track of the patients afterward. In some of these cases no positive secondary symptoms had followed, but there was always a doubt about such cases whether the diagnosis had been correct or not. In these cases he had traced the source from whence the disease had been acquired; but he assumed, from their history and appearances, that they were genuine cases of syphilis.

It would not surprise him very much to see some of these cases of excision, in which no secondary manifestations had followed, develop what was called tertiary lesions ten, fifteen, or twenty years hence. We saw so many cases where there had been no secondary lesions apparently, and yet the sequelæ showed that the disease did exist. We must recognize this fact, then, that there were a great many patients who had the secondary stage so slight that it escaped observation, and this was a source of a great deal of mistaken diagnosis, and assertions of success in treatment which had no real foundation in fact. Among other points of special interest alluded to in the paper just read had been that of hereditary syphilis. It was a question of great interest. He would like to say a few words in regard to this subject, and especially to look at it from the point of view which was taken by that most distinguished syphilographer, Mr. Jonathan Hutchinson, of London. He said that *syphilis was not an hereditary disease;* and he said distinctly that *syphilis was no more hereditary than small-pox, and was hereditary in the same way as small-pox.* It was the *disease*, and not a *diathesis*, that was communicated. This would be found in his article on syphilis, etc., published in London, in 1884, in a little work entitled "The Pedigree of Disease." This position was certainly a very startling one in view of the doctrine heretofore held by the profession at large. For his own part the speaker was quite willing to accept it. In point of fact, the views which he had held and advocated, first in his "Physiology and Pathology of Syphilis," published in 1880, made such a conclusion the logical sequence of the position assumed in that work. Afterward, in his work on "Genito-urinary Diseases and Syphilis," published in 1883, there occurred a chapter on the syphilis of infants and the so-called hereditary syphilis in which the question was considered from the standpoint of a gradual material syphilitic infection through a diseased cell or germ as opposed to the mysterious instantaneous doctrine held by most authorities, and the only logical deductions from these premises fully warranted the statement (first made by Mr. Hutchinson in 1882) that syphilis was never the result of hereditary transmission. It seemed to him that there were

many things that hitherto had not been understood which pointed to the truth of this teaching. For instanee, syphilis was said to be eommunicated by the male parent to the ehild by heredity. This was aecepted by almost all authorities. Now, it was likewise asserted by all authorities that the physiological secretions—sweat, milk, saliva, mueus, urine, tears, and *semen*—did not contain the eontagium. The latter was partieularly mentioned. They all mentioned it. If we referred to any of the transatlantie authorities, we should find this statement confirmed. Our own authorities — Bumsted, Taylor, Van Buren, and Keyes—all stated distinetly that it was well ascertained and aceepted that *the semen did not contain the contagium* of syphilis. If that was the ease, it would be interesting to know how they would answer the question as to how the male had access to the ovum—how the male could eommunicate syphilis to an embryo or to an unborn child. This was a question which it might be well to think of. The faets probably eould be shown to be that whenever the ovum, or fœtus, or child had syphilis—syphilis that had been aequired *in utero—the mother had first been infected;* that, if due to the male parent, he must necessarily have given the disease first to the mother, and she in turn to the ehild. Now, there was a curious fact spoken of by Diday. He said it was a well-known *law* that no woman eould communieate to her infant a syphilis which she had acquired not to exeeed two months previously to the birth of the ehild. So certain was Diday's belief in this law that he said he was willing to give to a healthy woman to nurse a ehild of a woman who had acquired her disease *not more than two months previous to her delivery.* Now, there were two months during whieh it was accepted as a clinical fact the child is safe. If the mother aequired her initial lesion only two months previous to the birth of the child, that ehild could not aequire syphilis *in utero.* The question at onee arose, Why was this? It was beeause the syphilitic poison was not yet in the blood of the mother, that it required *two months* at least for it to get into the blood of the mother, and then only eould she communicate it to the embryo or to the child. This also proved what had been stated in the paper of the evening in regard to the gradual infection of syphilis. Before this was understood, this rule of Diday could hardly be comprehended.

Dr. Bartlett, of Flatbush, remarked that all physieians having a large experienee with the criminal elasses knew but too well the moral, intellectual, and physical misery and degradation entailed by syphilis. In view of this, he thought that, in certain cases, both for the good of the eriminal and the protection of soeiety, a more radieal and serious surgical operation would be justifiable than the one proposed. The principle of heredity was so strong that society had the right to protect itself in these cases by preventing the possibility of procreation.

Dr. George R. Fowler took exception to the statement made by the essayist that tertiary symptoms of syphilis almost always occurred. The speaker was of the opinion that syphilographers of the present day maintained that tertiary symptoms, and particularly those of a severe type, were rather rarely met with. He further believed that it was a growing impression that syphilis in its protean form was, so to speak, "running out." The syphilis of to-day was not the syphilis of one hundred years ago, and many of the cases which were supposed to have escaped syphilis beeause of excision of the initial lesion were cases in which possibly no manifestation of the disease would have occurred at all. He alluded to the faet that in Auspitz's experiments, in those eases in whieh the characteristie sclerosis reappeared at the point where the ehanere had been excised, eonstitutional syphilis oecurred irrespective of the existence or non-existence of indurated glands prior to the excision. This must make it appear that there was a stage of the disease during whieh the condition of the glands, so far as we were able to determine it, had very little, if anything, to do with the development of the sequelæ, if the subsequent stages in their development might be so denominated. Dr. Leuf had said it was well proved, although not generally known, that self-inoculation was possible prior to systemic infection; and that brought us at once to the important point in the discussion of the question of the excision of the initial ehanere together with the indurated glands. The eases cited by Auspitz, in which eonstitutional syphilis occurred in spite of the faet that no induration of the inguinal glands took place prior to sueh development, suggested the possibility of channels of infection other than these lymphatics. He recalled a ease in which a surgeon removed a tumor of the testiele, and, while excising some indurated glands in the groin, accidentally pricked his thumb. In due course of time a syphilitic chancre made its appearanee at the site of the little wound, and this in its turn was followed by constitutional syphilis. Although the patient had denied venereal disease when admitted to the hospital, yet he acknowledged to the surgeon subsequently that ten years before he had had a sore upon his penis, for whieh he did not seek advice, and that the indurated glands in the groin had existed since that time. No other manifestation of the disease had ever occurred. If it eould be supposed that this patient had kept the virus stored up in these indurated glands for ten years, then we eould see our way clear, in a eertain proportion of cases, to a hope of benefit to be derived from exeising sueh glands as early as praetieable.

Dr. Leuf, in coneluding the debate, saw, in reference to the remarks of Dr. Otis, that that gentlemen had entirely misunderstood him. He had expressly stated that the primary lesion was not an ulcer. With referenee to the implication of the lymphatie vessels, if they were at all involved, perhaps whether they appeared to be involved or not, it might be most proper to excise them. As to the justifiability of the operation, he would say, if it was justifiable to extirpate a whole breast, to dissect away all the fat and superficial fascia down to the peetoralis major, and elean out the whole axilla because there was a little nodule in the breast, it certainly ought to be justifiable to remove from the end of the penis a small sore, and even a few glands and lymphatic vessels running therefrom. With referenee to Dr. Fowler's observation that syphilis was not so bad as it was one hundred years ago and was "running out," the speaker thought if that were so the operation might be justifiable on the ground that by its means it might be made to "run out" so much the quicker, and he thought it was not wise to exeise the lesion without scooping out the glands also. If these lymphatie vessels and everything in their immediate vicinity were excised, "eleaned out," he thought an additional safeguard would be effected, and he did not think the operation very dangerous. A surgeon of the enthusiasm of Dr. Fowler ought not to see any particular danger in it. Dr. Fowler had also referred to the possibility of there being some other channel of absorption on aceount of the non-infection of the glands, apparently. There seemed to be no other channel exeept the blood, and the speaker thought that idea had been refuted in the paper. If it was not through the blood, it must be through the lymphatie or other ehannels that he knew not of.

Miscellany.

The Ninth International Medical Congress.—Speaking of the action of the enlarged committee, the "Boston Medical and Surgical Journal" says:

"The committee did the work expected of it, and with less malice than would have been possible, but with sufficient thoroughness, we fear, to put an end to the prospects of a successful and creditable *international* congress, and adjourned to meet in St. Louis on the first Monday in May, 1886. The rules were amended so as to confine membership to the constituency of the American Medical Association. The American members, it is decreed, shall consist of delegates from the American Medical Association, and from medical societies in affiliation with it, each of these societies being entitled to one delegate for every ten members. The number of sections was reduced from nineteen to sixteen, and the presidents of sections are no longer *ex-officio* members of the General Committee.

"Dr. H. I. Bowditch, of Boston, was dropped from the list of vice-presidents, Dr. A. Jacobi from the presidency of the Section of Diseases of Children, Dr. Lefferts from that of Laryngology, Dr. H. P. Bowditch from that of Medical Education, and Dr. H. D. Noyes from that of Ophthalmology. Numerous changes and additions were made in the vice-presidents and members of council of the different sections. These honors are issued as plentifully as fiat money after a *coup d'état*, and the various geographical divisions of the country are impartially besprinkled with them. A publication of the full list would require much space; and, as this is already the second long list made public within a few months, as the refusal by many prominent men to serve as officers under existing conditions makes certain the appearance of other revised lists, which may eventually end in no list at all, we content ourselves with referring our readers to our news columns for the present organization of the Congress and for changes in the presidents and vice-presidents of sections. In the same columns will also be found a report of the action of prominent physicians in Philadelphia and Boston connected with the organization of the Congress. These refusals to accept office in the present organization will doubtless be followed by others.

"These gentlemen proposed to aid and participate in the discussion of questions of medical science, not of medical ethics, medical politics, or of square miles of territory. There will, however, be more offices, although less congress, for those who prefer such discussions and such distinctions to a harmonious gathering of scientific men searching for truth; and we hope somebody may be happy, if it be only for a short time."

In a very temperate article on the same subject, the "Maryland Medical Journal" says:

"Looking at the work of the General Committee, it seems to us that it has endeavored to make but few changes, and that it has performed the disagreeable duty assigned to it by the association in an extremely mild way. It has managed to make a few alterations in the chairmanship of the sections and to add a few college professors, formerly overlooked by the original committee, to the sections. It has, however, performed, in our judgment, the most stupendous work of supererogation ever exacted from a body of intelligent men. We are totally unable to see how the fortunes of the Congress have been a tithe benefited by the changes made. On the contrary, it has suffered immensely in the eyes of all unbiased thinkers by this unnecessary controversy about representation on sections and 'New Code' principles. As the Congress now stands organized, we much doubt its ability to attract that attention as a scientific body it was entitled to. How can those men interested in pure science feel that same interest in the fortunes of an organization handicapped with contentions for offices and ethics and weighted down with that ponderous body, the American Medical Association? It is truly an unfortunate circumstance which has happened to impair the usefulness of the International Medical Congress. While we still trust that wise counsels will prevail, that bitter differences will subside, that men will consent to work together in harmony for the success of the Congress, it seems quite clear to us that the Ninth International Medical Congress can not take the position it would have assumed under its first organization. It is an apt saying, Two wrongs can never make a right. The mistakes of the first committee—if such were made—have not been corrected by the present committee. We fail to see how the few changes which have been made in the officers of the Congress can do otherwise than impair its usefulness and drag it down to the level of a promiscuous social and semi-scientific gathering. It is a sad commentary upon the status of the profession in America that a petty squabble for a few positions should have marred what had promised to be one of the most noted scientific meetings ever held on American soil. What view our transatlantic brethren will take of this status of the Congress it is not difficult to surmise. We presume that the American Medical Association will enjoy the banquet it has prepared to its own eminent satisfaction, while the rest of the profession will look on from a distance. We can not but deplore the present outlook, and profoundly trust that the final result will be more satisfactory than present indications would seem to warrant."

The "Peoria Medical Monthly" says:

"We believe the whole trouble has arisen from personal grounds on the part of a few who were overlooked when the places of honor were distributed. It was purely a fight of the 'outs' against the 'ins,' and, now that the 'outs' have gained the field, the existence of the Congress is jeopardized.

"It can not be claimed that the American Medical Association at New Orleans represented the medical profession of this country, or if the claim be made it is a laughable one. And it can not be denied that the American Medical Association, with every similar body in the country, is more or less ruled by coteries and cliques.

"The situation is a deplorable one for the good name of the medical profession in America. Our European brethren will hesitate to attend the Congress at Washington in very large numbers, for they will have reason to fear that the factional feeling and jealousies of certain members of the 'rule or ruin' party in the American Medical Association will carry their fight into the Congress itself.

"What is to be done to remedy the trouble and preserve the good name of the profession of America? We do not know; perhaps the best thing that could be done would be to notify the Executive Committee of the last Congress that, owing to the war raging in the United States, the next Congress should be held elsewhere, either in Europe or Canada."

Science and Modern Discovery.—The present occupant of Sir Isaac Newton's professorial chair at Cambridge University, Professor G. G. Stokes, F. R. S., who is also secretary of the Royal Society of London, delivered a remarkable address at the annual meeting of the Victoria Institute, in London, toward the end of June. Professor Stokes gave an important account of the progress of physical science during the past quarter of a century, and, reviewing the results, specially noted that as scientific truth developed, so had men to give up the idea that there was any opposition between the Book of Nature and the Book of Revelation. He said that for the last twenty years or so one of the most striking advances in science had been made in the application of the spectroscope, and in the information obtained with regard to the constitution of the heavenly bodies. The discovery that there were in these particular chemical elements which were also present in our earth exalted our idea of the universality of the laws of Nature, and there was nothing in that contrary to what he had learned in Revelation, unless we were to say, as the heathen did, that the God of the Hebrews was the God of the hills and not of the valleys. Entering with some particularity into the composition of the sun, he said this gave an idea of an enormous temperature, since iron existed there in a state of vapor. This was utterly inconsistent with the possibility of the existence there of living beings at all approaching in character to those we had here. Were we, then, to regard this as a waste of materials? Might we not rather argue that as in animals we ascended by greater specialization, so we could consider the differentiation of office in different members of the solar system as marks of superiority, and could regard the sun as performing most important functions for that system? In fact, all life on our earth was ultimately derived from the radiation of solar heat. Referring to the doctrines of conservation of energy and of dissipation of energy, he pointed out at some length how the sun, so far as we could see, was not calculated for an eternal duration in the same state and performing the same functions as now. We must regard the universe on a grand scale, and then there was progress. If we contemplated nothing but periodicity, perhaps we might rest content and think things

would go on for ever as at present; but, looking on the state of the universe on a grand scale as one of progress, this idea obliged us to refer to a first cause. He concluded with recommending that the Annual Report of the society, read by Captain Frank Petrie, the honorary secretary, be adopted. It showed that the number of home, American, and colonial members had increased to upward of eleven hundred, and that the Institute's object, in which scientific men whether in its ranks or not aided, was to promote scientific inquiry, and especially in cases where questions of science were held by those who advanced them to be subversive of religion. All its members and one-guinea associates received its Transactions free, and twelve of its papers were now published in a People's Edition, which was to be had in many of the colonies and in America. The address was delivered by Dr. J. Leslie Porter, president of Queen's College, Belfast, the subject being "Egypt: Historical and Geographical," a country with which he had been thirty years intimately acquainted. Having referred to the antiquity of Egyptian records, which in so many instances bore on the history of other ancient countries, he proceeded to describe the various changes through which that country had passed since its first colonization; and, touching on its physical geography, concluded by giving the main results of recent exploration. He said: "Were the Nile, by some convulsion of Nature, or by some gigantic work of engineering skill—neither of which is impossible—turned out of its present channel away up to Khartoum, or any other point above Wady Halfa, Egypt would speedily become a desert." No tributary enters the Nile below Berber—that is to say, for the last thousand miles of its course. "The arable land of Egypt is about equal in extent to Yorkshire." The White Nile, issuing from Lakes Albert and Victoria Nyanza, is broad and deep, never rises above a few feet, and supplies the permanent source of the river of Egypt. "The other tributaries produce the inundation." Of these the *Atbara*, from the mountains of Abyssinia, is the most fertilizing, as it brings down with it a quantity of soil. The deposit of this soil is slowly raising the bed of the river as well as extending on each side; for example, on the plain of Thebes the soil formed by deposits has in thirty-five hundred years encroached upon the desert a third of a mile, "while the ruins of Hierapolis in the Delta, which once stood above reach of the inundation, are now buried in a mud deposit to a depth of nearly seven feet." In conclusion, he referred to Egypt and its present condition, saying: "The commerce from the upper tributaries of the Nile, and from the wide region of the Soudan, forms an essential factor in the prosperity and progress of Egypt."

How to avoid Night Calls.—A story is going the rounds (who started it we do not know) at the expense of the young physician who is always so busy that he doesn't know what to do. "I have got more business than I can attend to," boasted he to an old practitioner who knew he lied. "I had to get out of bed five times last night." "Why don't you buy some insect powder?" quietly asked the old doctor.—*Medical Age.*

Prizes for Electrical Appliances.—We learn from the "Chicago Tribune" that the McIntosh Company, of that city, received the first medal for fine displays of electrical goods at the New Orleans Exposition.

THERAPEUTICAL NOTES.

Glycerin as a Preventive of Trichiniasis.—Merkel ("Dtsch. Arch. f. klin. Med."; "Ctrlbl. f. kliu. Med.") relates the case of a man who ate a portiou, as long as one's finger, of a sausage in which living trichinæ abounded. Twenty hours after the ingestion of the sausage he was purged thoroughly with senna, and several specimens of the trichina, non-encapsulated, together with fragments of the parasite, were found in the dejecta. The next day he was given a tablespoonful of pure glycerin every hour until fifteen doses had been taken. This caused no unpleasant symptoms beyond thirst and a feeling of dryness in the mouth, and the man escaped trichiniasis, while others who had eaten of the sausage were attacked with the disease.

Naphthol.—Mr. W. J. Rigney, of New York, an analytical chemist, writes to us as follows: "The extraordinary power of naphthol as an antiseptic and disinfecting agent has been known for a long time, but its disagreeable smell and the difficulty of preparing it in a pure state, with the occasional toxical action of the crude naphthol, have been a bar to its use as a remedial and antiseptic agent. Justus Wolff, a chemist interested in coal-tar products, has recently succeeded in producing it in a pure and odorless state, in well-defined crystals, and states that its antiseptic action is much greater than that of carbolic acid. Recent research has demonstrated that the toxic effects of crude naphthol are due to the impurities it contains. Dr. Shoemaker, of Philadelphia, as he stated in a paper read before the Philadelphia County Medical Society, has conclusively proved the non-poisonous character of the purified or odorless naphthol by taking large doses internally. It has no corrosive action on the skin, and will not injure textile fabrics. As a remedial agent, it acts with greater efficiency than carbolic acid, over which it has many advantages, and the fact of its being absolutely odorless will make it a desirable substitute. It is expected that it will shortly be produced on a manufacturing scale as a substitute for carbolic acid."

A Gargle for Chronic Pharyngitis.—The "Union médicale" attributes the following formula to Bamberger:

Chloride of ammonium	75 grains;
Honey of roses	750 "
Water	12½ ounces.

To be used several times a day, together with mustard foot-baths, the use of tobacco being prohibited.

Belladonna in the Treatment of Intestinal Obstruction.—Dr. T. J. Hudson ("Med. Times and Gaz.") thinks that in these cases the best way to use belladonna is to apply the extract to the abdomen with very hot poultices, and to give one or two grains of the extract as a suppository every hour, or iuject $\frac{1}{120}$ of a grain of atropine every two hours until slight dilatation of the pupil is maintained. If the pain continues, and is serious, an injection of $\frac{1}{60}$ of a grain of atropiue, with $\frac{1}{8}$ of a grain of morphine, is the best, as it combats depression and nausea. Morphine alone often increases the obstruction by causing or increasing nausea and, in the early stage of intussusception, preventing the bowel from righting itself by its own muscular power. He adds the caution that lime-water should not be given, as it decomposes atropine.

The Treatment of Seasickness.—"In our own person," says a reviewer in the "American Practitioner," "the bromide availed not, nor would the Seidlitz stay down, but the Mellin's food was acceptable and useful, while a good article of kumys was most grateful to the palate and did much to allay nausea."

Hydrobromate of Quinine and Valerianate of Caffeine in the Treatment of Malarial Poisoning.—Cerededo ("Gazz. degli Ospit."; "Rev. méd.") concludes from numerous experiments that the hydrobromate of quinine is preferable to the sulphate for the following reasons: 1. Its activity is greater in moderate doses. 2. It acts as a nervous sedative. 3. It stops vomiting, a matter of special importance in certain countries. 4. It readily brings about a favorable change in the type of the fever. 5. Its bitterness is less marked. 6. It does not irritate the intestinal mucous membrane, and produces neither constipation nor diarrhœa. 7. It allows of the avoidance of too frequent subcutaneous injections. 8. It diminishes the probability of relapse. 9. When once the paroxysm has come on, if it can not reduce its intensity and duration, it should be administered in capsules, combined with valerianate of caffeine. 10. Given in that way half an hour before the paroxysm, it is capable of arresting the latter. 11. By combining the two salts (fifteen grains of the hydrobromate and seven or eight grains of the valerianate), we may check certain quotidian forms which are rebellious to much larger doses of the sulphate. 12. The action of this combination of the two drugs, given in comparatively small doses, is more powerful than that of any other salt of quinine in much larger doses.

The Treatment of Epistaxis.—Introduce into the nostril, to a considerable distance upward, a piece of fine sponge, cut to the size and shape necessary to enable it to enter without difficulty, previously soaked in lemon juice or vinegar and water. The patient is to be kept lying on the face for a length of time, with the sponge in place. This, says "Lyon médical," is the procedure employed by M. Siredey for controlling epistaxis in typhoid-fever patients.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M.D., NEW YORK.

(*Continued from page 63.*)

PART III.

ELECTRO-THERAPEUTICS.

WE have now discussed the essential points pertaining to electro-physics and electro-diagnosis, and there remains now for us to consider the uses of electricity in the treatment of diseased conditions of various organs and tissues.

Before we pass to details of the practical part it may be well for us to review in a general way some of the laws which should govern us in applying electric currents to the different tissues, and the objects to be attained by the employment of faradaism, galvanism, and static electricity.

GENERAL ELECTRO-THERAPEUTICS.

The rapidity and completeness of reported cures by the use of electric currents upon living tissues during the last quarter of a century leave no room for doubt that this agent is particularly valuable in the treatment of paralysis, neuralgia, spasmodic diseases, disturbances in the sensibility of the skin, and many disordered states of the brain, spinal cord, and peripheral nerves themselves. We have undisputed facts which prove also that blood may be coagulated with safety within some aneurysmal sacs by the galvanic current, that the life of the ovum may be destroyed in extra-uterine pregnancy, that animal tissues may be disintegrated by chemical changes induced within them by this agent, and that neoplasms may be removed without hæmorrhage by the cautery loop.

Our present ignorance of the molecular and nutritive changes in tissues (as the cause or result of disease) renders it impossible to do more than speculate upon the theory of the therapeutical action of electricity in many cases; but, on the other hand, our empirical knowledge of these effects is none the less valuable because we are unable to explain them. The same criticisms would otherwise hold good in reference to almost all of the drugs employed in medicine. None of us know exactly *how* they produce their specific effects.

Concerning speculation upon electrical effects on living tissues, Erb remarks as follows: "What appears more natural than that neuralgia and spasms could be relieved by the sedative action of the anode, with production of anelectrotonus, and that anæsthesia and paralysis could be cured by the exciting action of the cathode, with production of catelectrotonus? But, apart from the fact that we are not certain that an increase of irritability really occurs in one group of cases and a diminution in the other, it must be remembered that electrotonic action disappears very rapidly after the cessation of the current, while the curative effects of the current are more or less permanent."

Now, we may summarize the general principles which regulate the use of electric currents as follows:

1. They may exert, under certain circumstances, a *stimulating* or *irritating effect.* This is, perhaps, the basis of the most varied applications of electricity to disease.

2. They may exert, when properly applied, a *sedative action* on nerves or nerve-centers.

3. They may be made to exert a *catalytic action* upon neoplasms, enlarged glands, etc.

4. They are capable of causing *electrolysis.* This action is one which has lately come into prominence.

5. They create *heat* under certain conditions. The galvano-cautery is to-day assuming a very prominent place in some of the departments of surgery.

Let us now discuss each of these special actions separately, noting the general points of interest pertaining to each which will aid us in properly treating our patients. Electrolysis and the galvano-cautery have been treated of in previous lectures.

STIMULATING OR IRRITATING EFFECT OF ELECTRICITY.—This is indicated in many diseased conditions. Among these the following may be prominently mentioned:

Some of the various forms of cerebral and spinal diseases.

Depressed irritability of some special nerve-trunks.

Abnormal resistance to conduction of electric currents, exhibited by the motor or sensory nerve-filaments of some part.

As a counter-irritant to some pathological conditions.

Trophic disturbances of special regions (skin, nails, hair, etc.).

Vaso-motor depression.

Atrophic changes in muscles.

As a means of indirectly affecting the nerve-centers through the sensory nerves, thus influencing respiration, circulation, phonation, vaso-motor paths, peripheral organs, the muscles, etc.

The methods of application which are best adapted to accomplish irritating or stimulating effects are differently stated by authors. Personally, I do not confine myself exclusively to faradaism or galvanism.

The *faradaic current* is more commonly employed for this purpose than the galvanic. The electrodes should be selected, as to their size and shape, in accordance with the parts to be acted upon; they should be well moistened with salt water, and kept closely in contact with the skin. The wire-brush is the best electrode to stimulate the nerves or other tissues of the skin. It should be used dry. I prefer the secondary faradaic current to that of the primary coil for stimulating effects.

If galvanism is employed as a stimulant, Remak's plan, of moving the well-moistened cathode rapidly over the nerve-trunk or muscle to be stimulated, with a current sufficiently strong to cause strong wave-like contractions, is a good one. Another method, termed by this author "terminal labile stimulation," consists in stroking the tendinous

end of a muscle with the cathode so as to affect the entire length of the muscle. In both of these methods the anode is kept stationary upon some indifferent or neutral point—the center of the sternum by preference, or the nape of the neck.

One of the most vigorous methods of stimulation consists in rapidly changing the polarity by means of a commutator, when the galvanic battery is employed.

The Combined Current.—Another method which I employ (not generally mentioned in text-books) consists in connecting a galvanic battery, by means of a rheophore, with a faradaic instrument, thus bringing *both a constant and induced current* to bear upon the tissues at once. The rheophore which connects the batteries joins the positive binding-post of the galvanic instrument with the secondary coil of the faradaic; the two rheophores connected with the electrodes run from the negative binding-post of the galvanic and from the secondary coil of the faradaic instrument. The two instruments (faradaic and galvanic) are thrown into action simultaneously, and the strength of the current employed is graduated by the number of cells used in the galvanic battery and by the extent of the overlap of the secondary coil of the faradaic instrument. I have obtained some remarkable results by the stimulation thus produced in various forms of trophic disturbances of the skin and muscles.

The stimulation of nerve-fibers (when obstacles exist to their conduction) should be performed peripherally from the site of the lesion in sensory nerves, and as centrally as possible in motor nerves (Erb). Degenerated and atrophied nerves and muscles require a direct effect of the currents employed. For these reasons, the site of stimulating electrical applications depends upon the situation and character of the lesion and the object to be attained.

Modifying Effects of Electric Currents.—The *irritability of nerves and muscles* may be influenced by electric currents.

In certain diseased conditions we may expect a favorable result from such an action. Thus, for example, in some types of paralysis, in anæsthesia, in certain vaso-motor disturbances, and in depressed states of cerebral and spinal activity, the irritability of nerves or of muscular fibers is diminished; hence we resort to the so-called "catelectrotonic action" of electricity as a means of stimulating and restoring the normal irritability of the tissues affected.

It is now generally accepted as proved that *feeble faradaic currents* will accomplish this end. Galvanic currents, when applied for this purpose, give more positive results, however, than faradaic.

In order to *increase irritability* by galvanism, the negative electrode should be applied in a stabile manner (*i. e.*, without being moved) to the part upon which this effect is to be produced; and the strength and duration of the current should be steadily increased. When the muscles or motor nerves have been exhausted by over-exertion, excessive fatigue, etc., this action (termed by Heidenhain the "refreshing action" of galvanism) is particularly indicated.

Those conditions in which the *normal irritability of nerves or muscles is intensified* demand the so-called "anelectrotonic action" of electricity. These conditions comprise all irritative states of the sensory, motor, and vaso-motor tracts within or without the brain and spinal cord; hence we employ this action in neuralgias, spasmodic affections, hyperæsthesia of any of the cerebro-spinal nerves, headache, excitation of any of the special senses, cerebral and spinal irritation, etc.

In order to *decrease the irritability of nerves or muscles*, we may employ very powerful faradaic currents. We may also begin by employing a feeble faradaic current and gradually increasing its strength to the highest point of endurance; then maintaining it at this point for some time; and subsequently reducing it gradually to the feeblest current perceptible to the patient. This method is known as the "*increasing induction method.*" Electrodes well-moistened and of large size should be employed and kept immovable upon the same points during the application. It is often advisable to repeat this procedure several times at one sitting (Erb).

When the galvanic current is employed for the purpose of decreasing irritability, the positive pole is made fast at the point to be influenced. The current is increased in strength and maintained at its maximum for some time, after which it should be decreased gradually until it can not be perceived by the patient. The gradual decrease of the current-strength prevents the marked temporary increase of irritability which is liable to follow this method when this step is omitted.

Static electricity exerts in many cases an immediate beneficial effect upon neuralgic pains (especially upon sciatica) and upon the various spasmodic affections, as, for example, chorea, paralysis agitans, tremor, contracture, etc. These effects are obtained, in some cases, when galvanism and faradaism have proved of no benefit. I should never regard a case as incapable of benefit by electric treatment until static electricity, in the form of insulation, the electric wind, or the spark, had been thoroughly tested. I have had better results with this form of current in tremor than with galvanism or faradaism.

Some forms of pain (as, for example, the pains of ataxia, sciatica, trigeminal neuralgia, muscular rheumatism, etc.) are oftentimes relieved by a few applications of static electricity. My experience with this agent has convinced me that its effects are often satisfactory in cases where pain is a prominent symptom, when galvanism has been tried without benefit. I have found that insulation and the abstraction of heavy sparks from the seat of pain give the best results.

Catalytic Action of Electrical Currents.—Under this heading we include (1) an increase of absorption produced by dilatation of the capillary blood-vessels and lymphatics; (2) an increased capability of tissues for imbibition of fluids, through an increase of osmotic processes; (3) changes in the disassimilation and nutrition of nerves, on account of their stimulation or "refreshing effects; (4) changes in the molecular arrangement of tissues, caused by electrolytic processes; and (5) the results of the transportation of fluids from one pole to the other (Remak and Erb).

Remak has shown that muscles become congested and greatly swollen when subjected to galvanism. They are rendered tense, and (according to this observer) absorb water more freely than muscle which has not been galvanized.

Changes of a marked character may be indueed in the skin by galvanism. These have been studied by Erb, Remak, Bollinger, and others.

The vaso-motor nerves may be influenced by electrical currents. This is shown by many of the later investigations—prominently those of Lowenfeld, which demonstrate that contraction and dilatation of the vessels of the brain result, respectively, from antero-posterior and transverse currents through the head from a galvanic battery.

Although we are, as yet, unable to speak with positiveness regarding the certainty of the catalytic effects of electrical currents, or to map out the forms of disease which are to be regarded as specially indicating these catalytic effeets, still it may be said that the following states have been successfully treated by electrical currents, and that the cures are probably to be attributed to a eatalytic action: (1) Inflammatory affections of the nervous system, including sclerosis, myelitis, neuritis, etc.; (2) arthritis and chronic exudations into joints; (3) glandular enlargements; (4) hard cicatrices, periosteal swellings, and fibrous adhesions; (5) eontusions, sprains, extravasations of blood, and other results of traumatisms.

The *galvanic current* is the one that is generally employed when catalytic effects are desired. In diseased conditions of the brain, spinal eord, or any of the deeply seated organs, the faradaic currents are not usually productive of benefit.

The "stabile method" of application of the galvanic current is preferable, to my mind, when catalytic action is to be attained. The strength of the current should be sufficient to easily overcome the resistance offered, and the duration should be suffieiently prolonged to accomplish changes in the tissues subjected to its influence. One pole is placed, as a rule, at an indifferent point (the sternum by preference), and the other over the tissue diseased. Sometimes, as in the case of the brain, for example, the poles are placed upon either side of the diseased part. Although there are exeeptions to the rule, it is well to use the anode or positive pole over the diseased part when pain is present, when symptoms of active irritation exist, or when the morbid processes are very active. The cathode or negative pole is best adapted to influence chronic morbid processes, such as sclerosis, indurations, etc. Erb reeommends that the polarity of the eurrent be changed several times in either case; he doubts the infalhbility of the rule given, although it is theoretically sound. Chvostek urges the use of short and moderate currents for a few minutes (three to ten) when catalytic action is desired. In this way, he believes, the vaso-motor and trophic nerves are more impressed than by any other method.

Respecting the catalytic action of *faradaic currents*, a difference of opinion exists between authors of note. One thing is certain—viz., that strong currents are required, and that the currents must be passed directly through the diseased part to accomplish marked results. Glandular tumors have been resolved by this method with great rapidity in some reeorded instances.

(To be continued.)

Original Communications.

LEUCOPLAKIA BUCCALIS ET LINGUALIS, OR ICHTHYOSIS LINGUÆ;

SUCCESSFUL TREATMENT WITH THE GALVANO-CAUTERY.*

By E. FLETCHER INGALS, M. D.,

PROFESSOR OF LARYNGOLOGY IN THE RUSH MEDICAL COLLEGE, AND OF DISEASES OF THE THROAT AND CHEST IN THE WOMAN'S MEDICAL COLLEGE, CHICAGO.

During the past year it has been my good fortune to cure a case of the rare and intractable disease which forms the subject of this paper.

This disease has been recognized but a short time, and very little can be found upon the subject in general medical literature, but, by a thorough search in the library of the Surgeon-General's Office in Washington, I found about fifty papers, mostly reports of cases, which, with the single exception of one by Bazin, which I take second-hand, seem to embrace all that has been written concerning the disease.

The literature is involved in what at first seemed inextricable confusion, for the reason that several different affections have been confounded and described under the same name. Thus, "smokers' patches," the peculiar condition of the mucous membrane of the mouth found in old glass-blowers, termed by Guinaud † "professional patches," psoriasis linguæ, and various manifestations of syphilis, have been considered by different authors as true leucoplakia, or as one of its phases.

The term leueoplakia, which, of the names proposed for this affection, seems open to least objeetion, was suggested by Professor Schwimmer,‡ who gives a lengthy and exhaustive description of the disease. Ullmann # employed the term tylosis, which is strongly advocated by W. Fairlie Clarke.‖ The affection was first brought prominently before the profession by J. W. Hulke,△ under the title ichthyosis linguæ, a name which has been quite generally aceepted save by Debove ◊ and some other French writers, who have described it, together with other affeetions, as a manifestation of psoriasis.

Definition.—Leucoplakia buccalis is a chronic affection of the buccal mucous membrane, characterized by thickening of the epithelium, and the formation of white, opaline, elevated patches, which usually become fissured and painful, and, after continuing for a long time, are likely to terminate in epithelioma.

◊ Paris thesis, 1873.

History.—The first mention that I can find of ichthyosis linguæ is in a paper under the title of "Maladies de la peau," 1822, by Alibert, who records a case, reported in some of the journals, of a young woman in Naples who had extensive ichthyosis of the skin, which finally involved the tongue and lips. In 1837 Samuel Plumbe* described a case of enlargement of the papillæ of the tongue which he regarded as precisely similar in its nature to local ichthyosis of the skin. In 1858 Ullmann† described a case of leucoplakia under the name of tylosis. In the same year J. J. Buzenet‡ reported two cases of undoubted leucoplakia, and, in 1861, J. W. Hulke# recorded a case under the title of "Wart and Corn of the Mucous Membrane of the Tongue." The following year Sir William Fergusson‖ presented a somewhat similar case in a clinic at the King's College Hospital, and in the same year, in the report of a clinic by Dr. Andrew Clark,△ we find a case described under the name of aphtha figurata, which is supposed by some to have been true leucoplakia, but which seems to have been psoriasis of the tongue. The same year J. Moore Neligan◊ notes a case of true leucoplakia which finally terminated in epithelioma. February 28, 1865, J. W. Hulke,‡ of London, presented what is generally credited as the first paper on the subject to the Royal Medical and Chirurgical Society. Subsequently brief articles appeared on the subject by S. James A. Salter,↕ 1866; Bazin,‡ 1868; M. Lailler,** 1869; Sir James Paget,†† 1870; C. Saison,‡‡ 1871; and W. Fairlie Clarke,## 1872. Finally, in 1873, Charles Mauriac‖‖ published an exhaustive article on the subject under the title of "Du psoriasis de la langue et de la muqueuse buccale." Since Mauriac's article numerous papers have appeared, the most important of which are by M. G. Debove,△△ 1873; Henry Morris,◊◊ 1874; W. Fairlie Clarke,↕↕ the same year; Robert F. Weir,↕↕ 1875; Professor Ernst Schwimmer,‡‡ 1877 and 1881; and E. Vidal,*** 1883.

The disease is very rare, but its frequency can not be accurately determined, on account of the diversity of opinion which has been entertained by different writers with reference to its ætiology and diagnosis—a diversity which has caused many cases to be placed in this class which do not properly belong in it. Professor Schwimmer saw only twenty examples out of five thousand cases of diseases of the skin and syphilis, and many others have not seen so large a proportion as this; but doubtless many cases are not recognized, and pass for constitutional syphilis.

Most of the cases have been reported from Germany, France, and England, but some have been recorded in this country. So far the records show that the disease seldom affects any excepting males over forty years of age, though it has been observed as early as the thirty-second year, and a very few examples have been seen in women.

Anatomical Characters. — The patches are generally found on the dorsum of the tongue or the inner surface of the cheek and lips, but seldom, if ever, on the lower surface of the tongue or behind the anterior pillars of the fauces, and they are limited to the buccal cavity.

They may be seen in one or more small, irregular, or oval patches, or these may have become confluent. A considerable portion of the tongue alone may be involved, or the dorsum of the tongue, the buccal mucosa, and the surface of the jaw may one or all be affected.

The first appearance of the white patch is preceded by hyperæmia, and in the early stages a hyperæmic areola is found about its borders. Afterward the patch itself is more or less thickened, sometimes to the extent of six or eight mm., and the epithelium, which has become hard and dry, may be easily removed, or in spots it may have been spontaneously exfoliated, leaving the appearance of an ulcer.

The surface of the patch is marked by numerous fine lines or furrows, which intersect each other, dividing it into small polygonal spaces. Some of these may extend as deep fissures down through the thickened epithelium, and involve the mucosa in painful ulceration. In cases of long standing the papillæ may be much enlarged, giving the surface a warty appearance.

Under the microscope the epithelium is found greatly thickened, the papillæ enlarged and flattened, the blood-vessels dilated, with an accumulation of leucocytes about their walls. The superficial layer of the mucous corium is infiltrated with embryonic cells, and the deep layer is involved in vascular alterations.

According to Hulke,* there is hypertrophy of the epithelial and papillary layer of the mucous membrane, similar to the condition of the skin termed ichthyosis.

In 1874, W. Fairlie Clarke† spoke of the disease as a chronic inflammation and papillary growth, but in later writings he does not strictly adhere to these views.

Mauriac‡ says "it is certain that it is a chronic inflammation of the parts involved."

In the first stage of the affection, hyperæmia of the deeper layers of the epithelium exists, which is soon followed by exudation, and this consolidating causes induration.

The epithelial cells are increased and the papillæ enlarged, but later, when the affection merges into epithelioma, there is, according to Clarke,# an enormous increase of the rete mucosum at the expense of the papillæ, which are then reduced to mere threads.

Causation.—Excessive tobacco-smoking is ranked as one of the most frequent causes of the disease, but it is barely

possible that prolonged irritation of any character may have a similar effect on those predisposed to it.

Thus, Mauriac * and Vidal † mention highly spiced foods and alcoholic stimulants as irritants which must be avoided.

Schwimmer ‡ calls the affection idiopathic, but both he and Mauriac think there must be some peculiar predisposition toward it in order that it may be developed.

Bazin,# who has seen the affection in several members of the same family, believes that it is often, if not usually, the result of constitutional syphilis.

Mauriac believes that all psoriasis of the mouth and tongue supervening in syphilis is not necessarily syphilitic, and may not take part in the syphilitic disease.

Debove, Bazin, and Mauriac attribute it frequently to the arthritic or dartrous diathesis. Thus it will be seen that the cause of the affection is not definitely known, though it is commonly believed to be induced by smoking in most instances. It must not be forgotten, however, that several cases have been recorded in persons not addicted to the use of tobacco. In those who use tobacco to excess it is not necessarily the irritant effects of the smoke or heat that cause the disease, but, as in the case here appended, the noxious influence of the tobacco itself.

Clinical History.—It is also difficult to determine exactly the duration of the disease, for it has generally been discovered accidentally; but usually it will be found to have existed for months or years when the patient first presents himself. This is due to the fact that at first the affection causes no inconvenience. Usually the small patch first observed gradually increases in size until at length stiffness of the part occurs or painful fissures form, which cause the patient to seek advice.

In some cases the epithelial cells gradually pile up until a thick, horny mass is formed, which may then be thrown off spontaneously or pared off by the patient as he would cut off a corn or wart. After a time, varying from a few months to many years, the formation of fissures and ulcers causes pain, and finally, in a large percentage of cases, epithelioma results and runs its usual course. Sometimes the affection will remain stationary for months, or, under the influence of some irritant, it may rapidly progress, but may again become dormant if the irritant is removed. Occasionally unchanging erythematous patches remain in the surrounding mucous membrane for years.

In the cases associated with syphilis and in those that have developed into epithelioma the parts become greatly swollen, and deep, fungous ulcers occur which may erode vessels and cause serious hæmorrhage. In these same cases the lymphatic glands are involved, but this does not occur in the earlier stages of idiopathic leucoplakia.

Often the first symptom noticed by the patient is simply an uneasy sensation; but this may not appear until the disease has existed for years. In other cases the mucous membrane early becomes sensitive, so that spices, hot food or drinks, alcoholics, tobacco, etc., cause more or less pain. When deep fissures occur, the pain may become intense and almost constant, though in some cases it is present only at intervals. There are no constitutional symptoms until epithelioma is developed. Late in the disease, speaking, mastication, and swallowing sometimes become difficult, especially when epithelioma occurs. In such cases there is also profuse and very troublesome salivation, which continues both night and day.

Upon examining the mouth in the early stages, several more or less oval red or white patches are usually found which are apt to be mistaken for secondary syphilis. These in time become bluish, and finally, with increase in their epithelial covering, grayish or of a milky white color—like mucous membrane touched with nitrate of silver. These spots may remain distinct for a long time, but with the progress of the disease they become confluent, and at length form large, irregular patches. At first the surface of the patch is usually smooth, marked only by fine intersecting fissures, and is but slightly elevated above the surrounding mucous membrane. At this time the papillæ are often prominent and large, but, as the epithelial cells accumulate, they atrophy and are buried out of sight, and the surface may become raised several millimetres above the healthy mucous membrane. In some instances we find that a portion of the horny mass has been thrown off, and has left a central depression which may be ulcerated. These latter changes take place only in those cases which have been exposed to great irritation or which are approaching the stage of epithelioma. About the younger and growing patches we find an erythematous border, but this finally disappears. In cases associated with syphilis, cicatrices and nodosities or deep fissures of the tongue are usually found, and, in those which have passed into epithelioma, induration and thickening of the subjacent tissues, with deep, unhealthy ulcers, are likely to be present.

Diagnosis.—Leucoplakia is liable to be mistaken for what Guinaud * has termed the "professional patches," found in glass-blowers, for "smokers' patches," mercurial patches, psoriasis linguæ, syphilitic patches, and epithelioma unconnected with leucoplakia. The "professional patches" occur only in old glass-blowers, particularly in bottle-makers, and are found symmetrically upon both sides of the mouth, on the lateral surface of the jaw, and around Stenson's duct. "Smokers' patches" are more irregular in seat than those of leucoplakia, and are commonly located near the commissures of the lips, but not upon the dorsum of the tongue or inner side of the cheek. Again, the epithelium covering their surfaces is thin and closely adherent, so that it can not be removed, as in the disease under discussion. Mercurial patches are not so thick as those of leucoplakia, are never quite white, and are found on all parts of the tongue, but particularly where it is pressed against the teeth. According to W. Fairlie Clarke,† psoriasis is an affection in which circumscribed patches of epithelium assume a white, opaque appearance, which, after a day or two, are thrown off, when the epithelium is speedily restored; but soon other patches appear and go through the same course, until, after a time, the whole surface of the tongue becomes denuded and of a uniform red color,

* *Loc. cit.* † *Loc. cit.* ‡ *Loc. cit.* # *Loc. cit.*

* *Loc. cit.* † *Loc. cit.*

with crescentic markings or depressions, which, it will be observed, is very unlike the course of leucoplakia. Syphilitic patches are not so white as those of leucoplakia; they are usually round or oval, and more regular in form, and they seldom occur on the cheek, but are found principally on the tip or margins of the tongue, and often on its lower surface, which is never invaded by leucoplakia. Syphilitic patches do not become so thick as those of leucoplakia, and in syphilis the lymphatic glands are soon involved, which is not the case in the latter unless it has become cancerous. The pain is more severe in leucoplakia than in the syphilitic disease, and anti-syphilitic treatment causes no improvement, but may aggravate the affection. When syphilis and leucoplakia co-exist, the diagnosis is difficult, and sometimes can only be cleared up by specific treatment. Cancer arising without previous leucoplakia is distinguished from the latter by its history. In cancer, the induration of tissues and the final ulceration are not preceded by the chronic white patch, and are attended by more constant pain, with profuse salivation and a very offensive odor.

Prognosis.—The duration of the disease is uncertain One authority mentions two cases in which cancer supervened in less than six months. Sir James Paget * mentions one case which terminated in cancer at the end of eighteen months, several of Mauriac's † were of eleven to thirteen years' duration, while of the two cases seen by Hulke, ‡ which terminated in this way, one had existed twenty years. Others have mentioned cases of thirty to forty-five years' duration. Debove # and Bazin, ‖ who make no clear distinction between leucoplakia and syphilis, and Kaposi, △ who speaks of leucoplakia as a universal product of syphilis, very naturally believe that the affection is frequent, that it does not terminate in cancer so often as we should suppose from the writings of others, and that it is very amenable to treatment. Schwimmer ◊ says that the disease is frequently transformed into malignant formations and ends fatally, and the general belief is that it is very likely to end in epithelioma. Vidal ↕ believes that one half the cases terminate in this way. On this point Mauriac ↕ says that "transformation into epithelioma has often been noted, therefore it is important to cure the superficial affection, or it may pass into a deep, destructive, mortal disease."

The same author thinks that there are three varieties of leucoplakia (or, as he terms it, psoriasis linguæ). One, which he says is curable (due to syphilis), we do not think belongs to this class of diseases. The others he considers incurable. The variety which he attributes to the arthritic or dartrous diathesis he terms innocuous, while the third variety—the epitheliomatous—is incurable and malignant.

Among the indications that leucoplakia is passing into epithelioma are: non-inflammatory enlargement of the lymphatic glands, with exfoliation of the thicker portion of the patch, the formation of an ulcer, the supervention of sharp pain, salivation, and at length induration of the subjacent tissues. Finally, great swelling in the region of the jaw is likely to occur, and death takes place from exhaustion.

Treatment.—In cases of leucoplakia all sources of irritation, particularly those resulting from the use of tobacco and alcoholic stimulants, should be at once removed, and if the digestive organs are deranged, as is frequently the case, they should receive proper attention. Aside from these measures, most authorities believe treatment of little or no avail. Schwimmer * says that local* treatment is not rational; that alkaline washes and the waters of Vichy and St. Christan, and other alkaline waters, though highly recommended by Bazin † and other French writers, are not satisfactory in their effects; and that, even if improvement does occur under their use, it is not likely to be enduring. Debove ‡ and Bazin state that many cases of buccal psoriasis may be cured, but their favorable results may be due to the fact that they included many syphilitic cases in this class. By an examination of Debove's recorded cases, I find that, exclusive of the syphilitics, none of the patients seem to have been entirely cured, though many were treated by both Bazin and Debove, and a number are reported as "something better" after several months of treatment. Mauriac, # who believes that there are three varieties of leucoplakia—viz.: 1, the dartrous and arthritic; 2, the syphilitic; 3, the epitheliomatous—recommends arsenic and alkalies for the first, mercury and iodides for the second, and surgical measures for the third; however, he urges great prudence in using any of these measures, and states that the internal remedies have been found almost useless, and that mercury and the iodides are dangerous in the absence of syphilis.

For local application, the caustics which have commonly been employed are nitrate of silver, chloride of zinc, tincture of iodine, and acid nitrate of mercury; but none of them seem to do any good excepting in syphilitic cases, which I do not include under the term leucoplakia. Soothing applications seem to have been most beneficial, but they give only temporary relief.

E. Vidal ‖ says that "mercury and iodide of potassium aggravate the disease the more advanced it is," and that in the papillomatous state they precipitate epithelioma. When the affection has passed into epithelioma nothing can be of much benefit excepting thorough excision, but even this has not often been followed by happy results.

Henry Morris △ advises that, after other measures have been fairly tried, if the epithelium is constantly thrown off, leaving abrasions or ulcerations which are painful, the tongue should be excised without delay. He states that "the prospect of curing, or even much improving, ichthyosis by treatment is most unfavorable."

S. James A. Salter ◊ reported a case, which seemed to have been leucoplakia, which was cured by extirpation and cauterization of the wound with the actual cautery. In the case which I report it will be observed that internal remedies did no good, and that local applications of tincture of iodine, nitrate of silver, and the acid nitrate of mercury greatly increased the patient's sufferings, and would doubtless have aggravated the disease had they been persisted in;

but, as soon as the actual (galvanic) cautery was employed, relief from all pain was obtained, and by a persistent, careful use of it the disease was eradicated.

In considering this favorable result, of course we must not overlook the reported tendency of the disease to recur; but the fact remains that the belief in this tendency is based on a study of cases in the majority of which the diseased patch was never entirely removed. In my case the mucous membrane is perfectly healthy after a lapse of four months; therefore I believe the treatment adopted for it will prove curative in many cases if applied before epithelioma has developed.

From a study of the literature of this subject, and from my own small experience, I arrive at the following conclusions:

1. Leucoplakia buccalis is an idiopathic disease, distinct from psoriasis, "smokers' patches," and syphilis. It is largely confined to men past middle life, but it occasionally occurs in women.

2. The disease is so commonly found in inveterate smokers that the abuse of tobacco may fairly be considered as an exciting cause, though cases occur where tobacco has never been used.

3. The affection is chronic and, finally, in a majority of cases, terminates in epithelioma.

4. Internal treatment and the local application of sedative, stimulant, or caustic drugs are, in nearly all cases, either useless or injurious, and the latter are sometimes disastrous by hastening the development of epithelioma.

5. The actual cautery or the galvano-cautery will probably enable us to cure many cases if they are treated sufficiently early, provided it is applied to only a small spot at each sitting, and carefully, so as not to destroy the healthy tissues beneath the changed epithelium.

A Typical Case.—L. C., aged forty-three, printer, came to me in September, 1884, complaining of a sharp pain in the left side of the mouth, particularly when eating. This, he said, began two years before, when he had a tooth drawn. Two months later he first noticed a small white patch on the buccal mucous membrane. Upon examining the mouth, I found a large, irregular, milk-white patch, extending from the border of the gums down through the gingivo-buccal groove, upward along the left cheek, and from the first bicuspid tooth, in front, to the last molar, behind. Altogether this was as large as a silver dollar; its surface was marked by fine intersecting lines, which divided it into numerous polygonal spaces.

At the center of the patch, on the buccal surface, was a depression about 3 mm. in depth and 1 cm. in diameter, surrounded by elevated, hard margins, which gradually became thinner toward the edge of the patch. This margin was deeply fissured in two or three places. About half an inch in front of the anterior portion of this patch, on the under lip, was a small, white, warty growth, about 4 mm. in height by 3 mm. in diameter.

A critical investigation of the case failed to discover any history or signs of syphilis or hereditary disease. The patient chewed tobacco to excess and had smoked occasionally. He stated that previous to the removal of the tooth, and until the pain became troublesome, he had been accustomed to carry his quid of tobacco in the left side of the mouth, at the location of the patch. His general health was perfect, and he had never suffered from rheumatism or eruptive diseases, and did not use alcoholic stimulants. During the first few months of the affection pain came on about once in two weeks and would last several hours, but the attacks gradually became more frequent, until seven or eight weeks before I saw him, during which time the pain had been constant and often severe. The patch had been cauterized occasionally with nitrate of silver, but was never benefited.

When I first saw the case, suspecting that it might be syphilitic, I ordered iodide of potassium in large doses and directed that tobacco be discontinued. I cauterized the patch with tincture of iodine, but the application caused such severe and protracted smarting that I began at once to be doubtful about the character of the disease. Three days later I applied the solid nitrate of silver to a small portion of the patch, with similar results, and four days later the acid nitrate of mercury. This last application caused intense pain that lasted about seven hours, which, he said, drove him nearly crazy. I was now convinced that the disease was not syphilitic, and had the patient see Professor Hyde, who pronounced it leucoplakia. I next cauterized the central depressed portion of the patch with the galvano-cautery, which caused momentary smarting, but perfectly relieved the severe pains from which he had suffered for weeks, and they never returned. Two days later I destroyed the small, wart-like projection in front of the large patch, and subsequently, about every fifth or sixth day, I cauterized a small spot, nearly a centimetre in diameter, at the edge of the patch. These cauterizations were so superficial that only the epithelium was destroyed, the membrane beneath being but slightly burned; indeed, so light were they that a few times I was obliged to again cauterize the same spot before all the epithelium was destroyed. I found that as these cauterized places healed the mucous membrane appeared natural, and finally, after about thirty applications of the cautery, the entire surface presented the appearance of healthy mucous membrane, showing only two or three small cicatrices, where the cauterizations had been unusually deep. The iodide of potassium, which did no good, was discontinued soon after I began the use of the galvano-cautery. Now, at the end of four months after the last cauterization, the mucous membrane remains perfectly healthy.

NOTE ON THE USE OF ANTIPYRINE IN SUNSTROKE.

By BENJAMIN F. WESTBROOK, M. D.,
PHYSICIAN IN CHIEF TO THE DEPARTMENT OF DISEASES OF THE CHEST, ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

My object in publishing this note is to call attention to the use of antipyrine in two cases of sunstroke, so that others may, if they think proper, test it and contribute the results of their experience.

It occurred to me that the prompt introduction of an antipyretic dose of this substance into the subcutaneous tissues might be of great service in reducing the temperature, and so give time for attention to the treatment of the other pathological conditions. The ambulance surgeon, Dr. Folker, was therefore requested to provide himself with a fifty-per-cent. solution, and, in the event of his being called to a case of the apoplectic form of the disease, to administer a drachm of the solution hypodermically at once, and to repeat it in an hour, if the temperature was not markedly reduced. Other measures for the relief of the patient were, of course, not to be neglected.

On Saturday, the 18th, when the thermometer registered 99° F. in the shade, he was called to attend a young Englishman, twenty-two years old, of very robust habit, who, after working out of doors all the forenoon, became comatose and convulsed after reaching his home at midday. The head was congested, eyes suffused, pulse rapid and strong, skin dry, and the coma profound. The bowels had moved spontaneously, and he had vomited freely. The rectal temperature was 109° F. The doctor administered a drachm of the fifty-per-cent. solution of antipyrine hypodermically, applied ice to the head, and removed him to the hospital.

In the confusion attending his admission the exact time was not noted, but in about three quarters of an hour after the first dose the rectal temperature was 107·50° F. Cold was applied to the body and head by means of towels wrung out of ice-water and frequently changed; and another drachm of the solution was introduced under the skin. In thirty minutes the rectal temperature was again taken and found to be 99° F. The cold applications were at once discontinued and dry heat was applied to the surface, while whisky was injected subcutaneously.

When I arrived shortly afterward the surface of the body was cool, the pulse 120, the coma profound, and all the limbs were twitching convulsively. The head was still congested, the conjunctivæ injected, the pupils contracted but responding feebly to light, and the respiration was irregular and accompanied by a loud expiratory groan, such as is heard in severe cerebral disturbance. I gave two ounces of whisky and forty grains of chloral hydrate by enema, but they were not retained. About half an ounce of whisky was then given hypodermically. In half an hour the temperature began to rise slowly, so that the surface was warm. The twitching of the voluntary muscles became more marked, and he was seized with a most violent tetanic convulsion, which was controlled by chloroform. As the convulsions succeeded each other with increasing rapidity and intensity, I opened the median basilic vein and withdrew thirteen ounces of blood. The bleeding was terminated sooner than was desirable by the onset of a terrific convulsion, during which the arm was twisted violently and the opening in the vein occluded. After this there were no more severe convulsions; the patient became more quiet, and the rectum retained forty grains of chloral hydrate. This was followed by a

period of rest, during which the axillary temperature was taken and found to be 103·75° F.

One drachm of Lente's solution was thrown under the skin, and repeated about once in two hours till four doses were administered. At 8.15 P. M., as slight convulsions had occurred from time to time, six leeches were applied to the temporal regions, twenty grains of antipyrine given hypodermically, and forty grains of chloral hydrate by the rectum. From this time on he slept quietly, the temperature slowly declining until Sunday morning, when it was 99° F.

At about ten o'clock on Saturday evening the patient first became sufficiently conscious to partially respond when spoken to, and from this he passed into a condition of hebetude, which, by Monday forenoon, had given place to complete consciousness. The temperature has been normal since Sunday afternoon, though the pulse is still somewhat rapid. He takes nourishment well. From Sunday morning to Monday morning he had forty grains of sodium bromide every two hours, and five grains of the sulphate of quinine every four hours. The doses were then reduced to twenty grains and two grains.

This case represented the severest type of sunstroke. I have never before seen so bad a one recover. The temperature was high, the coma very profound, and the convulsions the most terrible that I have ever witnessed, except in one case of tetanus, the subject of which died within twenty-four hours after the diagnosis was made. The rapid and permanent reduction of temperature, which must have been mainly due to the antipyrine—inasmuch as the cold applications were only continued for half an hour—undoubtedly contributed toward the favorable result by giving time and removing at once the injurious effect of the hyperpyretic blood upon the higher nervous centers. The beneficial effect of the abstraction of blood was evident.

The second case was brought in an hour or two after the first, and while I was in the hospital:

The patient, an Italian laborer, had been engaged in some laborious work upon the new building of the St. John's Orphan Asylum, which was destroyed by fire last winter. He became suddenly unconscious, had well-marked convulsions, and voided his excrement involuntarily. When Dr. Folker, our very competent ambulance surgeon, arrived he was comatose, breathing irregularly, with rapid and tense pulse, suffused conjunctivæ, dry skin, and continual convulsive twitchings of all the voluntary muscles. The rectal temperature was 110° F. The doctor gave him a hypodermic injection of one drachm of the fifty-per-cent. solution of antipyrine, applied ice to the head, and brought him to the hospital. On his admission he was comatose. The surface, to my surprise, was cool. The pulse was 120, as nearly as it could be counted, with marked tension and a laboring stroke of the heart. The respiration was rendered irregular by the continued spasmodic movements of the voluntary muscles.

The convulsive movements of the limbs were very peculiar, differing from any that I had seen before, in that they were rhythmic in character, and most readily likened to those of a man pulling upon a rope. The rectal temperature, thirty-five minutes after the administration of the hypodermic injection containing one half drachm of antipyrine, was 101° F.

No cold applications were used in this case, with the exception of ice to the head. He was given, by enema, four ounces of whisky and thirty grains of the hydrate of chloral, and retained it.

After a time he became quiet, the convulsive movements almost entirely ceased, and consciousness became dimly perceptible. But, upon changing him to another bed, the peripheral irritation threw him into an active tetanic convulsion, which, however, soon subsided spontaneously. It was noted afterward that any pronounced peripheral irritation would produce convulsive movement. After an hour he received another half-drachm dose of chloral hydrate, with two ounces of whisky, *per rectum*.

He also received a drachm of Lente's solution of quinine about once in two hours. On Sunday morning he was quite conscious. The temperature was 99° F. He was ordered twenty grains of the bromide of sodium every two hours and three grains of quinine every four hours. On Monday his condition was still better, his mind, apparently, quite lucid, and his desire to move about and partake of food very decided. The bromide and quinine were continued.

The favorable termination in both of these cases is significant, as they were both accompanied by great hyperpyrexia and signs of a most profound vital disturbance. The first case was, probably, slightly injured by the use of cold applications too long continued, but this was quite excusable on the part of the house staff, as they were dealing with a new remedy, and had been advised not to neglect the old ones. The result in the second case would seem to strongly indicate that, where antipyrine is used, the external application of cold is not necessary. Another interesting observation was that, when the temperature declined, the cerebral symptoms still continued. This might indicate that even a short period of such intense heat and arterial excitement may so benumb the vaso-motor apparatus that several hours are required for recuperation.

If this is the correct inference, an agent like antipyrine, which is capable of reducing the temperature quickly, may be of the utmost importance.

But, of course, further observation is necessary before any positive conclusion can be drawn. From our experience so far, I should say that half a drachm of the drug would be sufficient to accomplish the purpose. A fifty-per-cent. solution is easily made, and, when injected beneath the skin, produces very little irritation.

CHOLERA ASIATICA AND CHOLERA NOSTRAS;

THEIR DIAGNOSIS AND TREATMENT,

WITH SPECIAL REFERENCE TO THE BACILLUS.

By ARNOLD STUB, M. D.,
BROOKLYN.

(*Concluded from page 36.*)

Those spirilla discovered by Deneke in cheese, and by Lewis found in the mucous covering of the teeth, I have nothing to do with in this paper; it will be sufficient, I think, to mention that they also present different appearances on cultivation, and that Dr. Lewis's bacillus does not grow at all in alkaline or neutral nutritive gelatin. If a small particle is taken, with a previously well-sterilized platinum wire, from one of the colonies recognized as Asiatic-cholera bacilli, and gelatin kept in a test-tube inoculated with the same, we shall find that within forty-eight hours, at 68° F., from the time of inoculation, a whitish turbidity

will start, in the immediate neighborhood of which the gelatin will become liquefied; but this process is so slight that only a very fine capillary tube will be the result, which becomes a little wider toward the surface. The top of this tube is generally below the level of the solid gelatin, and upon the top of the tube we generally see an air-bubble. The liquefied gelatin remains clear, and only upon a few places do a few whitish masses appear. After four to six days the gelatin will be sufficiently liquefied to reach the walls of the test-tube. The spirillum of cholera nostras, however, is characterized by its very energetic liquefying action upon gelatin.

Within twenty-four hours it has formed a wide tube filled with a diffuse opalescent fluid, and the surface of this tube extends to the walls of the test-tube. The lower end of the tube is widened out sack-like. I may add also that the cholera spirillum does not grow upon potatoes at a temperature less than 86° to 88° F., and from 98½° to 99½° F. it forms a dark-brown paste upon the surface. The spirillum of cholera nostras grows beautifully upon potatoes at 64·5° F., and forms a yellowish-gray covering.

However, before I proceed to make a cultivation of the bacilli to be found in the alvine evacuations, I first make an attempt to relieve the patient by a hypodermic injection of sulphate of morphine and atropine. I order frictions with soap liniment, chloroform, and laudanum to the body; also sinapisms alternately applied to the extremities and epigastrium, hot flat-irons or bottles filled with hot water to the soles of the feet, and try to administer a good dose of 10 to 15 grains of calomel internally, and order the same to be continued in small doses of about two grains every two hours.

I certainly shall not give bismuth, either the subcarbonate or the subnitrate, because I wish to avoid everything which tends to make the contents of the stomach and alimentary canal more alkaline. I do not expect anything from the calomel except from its property as a mercurial to destroy the cholera germ by acting as a poison directly upon the latter; and perfectly agree with the views of Dr. Pallen, of New York, who published the same in the "Medical Record" of March 7th, and who contended that during cholera the stomach and alimentary canal were not capable of assimilating any medicine whatsoever. For this very reason I shall also continue the hypodermic injections at proper intervals, and in accordance with the urgency of the case. Later on, when the condition of the patient requires it, I shall also administer brandy hypodermically.

But, gentlemen, I shall also remember the results of the treatment of Professor Cantani, of Naples, who, during the last epidemic, resorted to acidulated enteroclysmata of a temperature from 103° to 104° F. According to Koch, one part of carbolic acid to 400 parts of water is sufficient to prevent the increase of the cholera bacilli, and, although we should not be justified in administering such a clysma to a healthy person, I believe that, in case of cholera where all the powers of absorption by the intestinal canal were suspended, we might perhaps be able to resort to this proportion with benefit to the patient. Although Professor Armanni, of Italy, has found the microbes principally in the colon and cæcum, and a number of cases have been treated with simple medicated enemas with benefit, in severe cases, where the inroad of the microbe extends higher up, it will be necessary to resort to an enteroclysma which will reach beyond the ileo-cæcal valve.

Of all substances, however, which prevent the reproduction of the cholera bacillus, the bichloride of mercury stands foremost. Oil of peppermint has this property in the proportion of 1 to 2,000, sulphate of copper 1 to 2,500, quinine 1 to 5,000, and the bichloride of mercury 1 to 100,000. For this reason I would try the sublimate in combination with hydrochloric acid: first as an ordinary enema, and later on, if I found the disease make progress and the case become desperate, as an enteroclysma. If, however, I were able to dust the whole of the alimentary canal over with calomel in the same manner as we sprinkle iodoform over an ulcerated surface, I think I should prefer the latter method to kill the microbe.

I am not aware that the sublimate has been tried in the manner proposed by me, and I certainly would abstain from its use in the beginning of the disease and before the faculty of absorption had ceased. The algid stage, I think, would be the proper time to begin with, and previous to it I should confine myself simply to copious enemas of hot water acidulated with hydrochloric acid, and administer the latter also by the mouth in the form of an iced lemonade to relieve thirst.

Whether an occasional enema or an enteroclysma of hydrochlorate of quinine, dissolved in hot water and acidulated with hydrochloric acid, would be desirable, I think a matter worthy of consideration.

Gentlemen, we put a typhus-fever patient into an iced bath with the view of reducing his temperature. Would it be unscientific and unpractical to put a cholera patient into a *permanent* hot bath with a temperature, say, of 104° or over to increase his temperature? Koch considers the manner in which the cholera bacillus produces certain changes in the system a poisoning process, and states that in his opinion the poisonous properties of the bacillus act with paralyzing influence upon the circulatory apparatus, and, although this seems to be only theoretical so far, it would explain the fact that hot baths have proved of benefit in cholera. I must also allude to the transfusion of salt water into the venous system as advocated by Dr. Kronecker, who also gives a description of an apparatus to be used for the purpose, and who condemns the practice of intra-abdominal and subcutaneous injections, frequently resorted to during the last epidemic in Italy, on account of the impossibility of regulating the time when the injected fluids may enter the circulation.

During the same epidemic the following treatment was adopted. Cantani, Paoluzi, and particularly Dr. Vitone, speak of the excellent results of a clysma composed of

Inf. flor. camomill (38° C.)	2 litres;
Acid. tannic	3,0–6,0 grammes;
Gumm. arab	30,0–50,0 "
Laudanum	30,0–50,0 "

which, freely administered, caused intermissions of from six to twelve hours. With all internal remedies for the pur-

pose of disinfecting no result has been obtained. But all Italian authorities agree that subcutaneous injections of morphine have been of benefit. Of special benefit, however, have been irrigations *per rectum* of carbolic acid, sublimat, iron sulphate, and quinine.

In the algid stage Cantani has resorted, with considerable benefit, to subcutaneous injections of salt water of the temperature of about 100° F. and in the proportion of thirty-four ounces of water, sixty grains of table-salt, and forty-five grains of carbonate of sodium.

He observed in the severest cases an abatement of all the urgent symptoms within a few minutes after this enema had been given. During the stage of asphyxia, subcutaneous injections of ethereal tincture of valerian, ether, and sulphate of caffeine were used.

The Italians also speak highly of hot baths and of the inhalations of oxygen. Cantani especially mentions that during convalescence we must be careful to avoid milk and beef-tea or meat broths of any kind, because the comma bacillus is apt to grow in those media and a relapse may be the consequence. But between the two he would prefer meat broths, because he found that milk never did agree with his patients. His meat broths he acidulated with hydrochloric or lactic acid. In case, after the strength of the patient has returned, vomiting persists in consequence of hyperæsthesia of the stomach, he recommends ether and chlorodyne, or cherry-laurel water with morphine or belladonna.

Dr. Dornbluth, of Rostock, recommends calomel to be given as I have recommended before, and particularly in the typhoid stage he calls attention to resorcin and cotoin. He speaks highly also of subcutaneous or intravenous injections of salt water, to overcome the thickening of the blood. During the epidemic in Toulon the treatment of the so-called cholera diarrhœa consisted of

℞ Æther	.....	1,0;
Tinct. opii	..... gtt.	xv–xx;
Ext. krameriæ	.....	1,0;
Syr. cort. aurant	.....	30,0;
Aq. melissæ	.....	120,0.

Against the vomiting, every quarter of an hour a teaspoonful of Chartrense, sometimes bismuth and opium.

In more serious cases this treatment is combined with injections of warm wine and laudanum, carbonic-acid water cooled on ice, and, against profuse diarrhœa, water saturated with oxygen gas, to which I personally beg leave to object, as the cholera bacillus belongs to the species of aërobe bacteria and requires oxygen to develop. Frictions with ol. terebinthinæ, opodeldoc, and chloroform are used. Hypodermic injections of morphine in the epigastric region are particularly mentioned by Dr. Cuneo, physician-in-chief of the navy of France, who has found great benefit from the hypodermic injection of half a centigramme of hydrochlorate of morphine with one quarter of a milligramme of atropine. Spasm of the muscles of the lower extremities he has treated successfully with hypodermic injections of ether.

During the stage of asphyxia, injections of ether prolonged life for a few hours in a few cases, but subcutaneous injections of atropine sulphate, first one half a milligramme and afterward one milligramme, from four to five times in twenty-four hours, caused a rise of temperature of 2° in one case.

He also professes to have saved six patients with inhalations of pure oxygen by means of a mask and a tube, the latter introduced into the nares. In those cases where coldness and cyanosis did *not* form the prominent symptoms, this treatment, which he, by the way, repeated every half-hour, and continued for two minutes each time, gave no results.

The question of prophylaxis requires consideration in this paper, and I would like to call attention to the remarks made at the meeting of the Imperial Board at Berlin, July 24, 1884, by Dr. Leyden, that a certain immunity exists against a second attack of cholera, although this immunity does not seem to be absolute, and it is well authenticated that persons have been attacked by cholera in one epidemic and died during a second attack in another epidemic. More rare, however, is the fact that a person has been attacked more than once during one epidemic, although Dr. Wievioroevski quotes the case of a patient who was taken sick August 13th, left the hospital well on the 20th, and was taken sick again with cholera on the 5th of September, and died. Dr. Koch, however, thinks that such cases must be very rare, and seems to be of the opinion that one attack secures the person against a second attack during the same epidemic in most cases. Perhaps being impressed with the same views, a Spanish physician inoculates his clients with the comma bacillus, as I have read in a daily paper. It is remarkable, however, that the medical papers are silent upon the subject, or that they only give short notices of Dr. Ferrán's investigations.* If Dr. Ferrán's microbes are identical with Koch's bacillus, it would appear impossible to inoculate them into the blood with any chance of success, because the circulatory system does not seem to be the home of this parasite. In none of the post-mortem examinations Koch has made could he detect this parasite outside of the alimentary canal, and only very rarely in the contents of the stomach. If found in the latter, it has been only in cases where a process of regurgitation had caused fæces to enter the stomach. The blood and other fluids of the body are not invaded by the bacillus, and not a single case is on record where infection has taken place from a post-mortem examination. Whether Koch's comma bacillus assumes different properties if cultivated and recultivated upon different nutritive media, is a question which later investigations will certainly solve. If I may venture upon an opinion at all in this matter, it is that, if artificially cultivated bacilli have the property of causing immunity from a severe attack of cholera, they should be introduced into the intestine and not into the circulation. The question naturally forces itself upon me, Is this microbe of Dr. Ferrán's actually identical with Dr. Koch's bacillus, or is it the same Dr. Emmerich, of Munich, has discovered in the blood and in the tissues of the whole body of persons who died of cholera?

* Only the "Deutsche medicinische Wochenschrift," of Berlin, April 20, 1885, speaks of the fantastic views of Dr. Ferrán in reference to his inoculation of the bacillus.

Dr. Emmerich also cultivated his bacterium, and inoculated various animals with the same. They all died, but post-mortem examinations seem to have revealed the fact that Peyer's patches were ulcerated, which led critics to assume that those animals did not die of cholera but of a septic poison. Koch has made about one hundred post-mortem examinations in Egypt, India, and France, and in all cases the result has been the following. He divides the results of his investigations into three different varieties. First, he mentions cases where the lower part of the ileum and cæcum, and particularly above the ileo-cæcal valve, had assumed a dark-brown, reddish color, the mucous membrane being studded upon the surface with hæmorrhagic exudation. In a few cases he found diphtheritic patches, and the membrane almost necrotic. In accordance with this, the contents of the bowels were not of rice-water appearance, but a bloody, stinking fluid. In the second class of cases the redness was less marked, being only by spots, and in some cases only the edges of the follicles and Peyer's patches were reddened. The last form he considers to be particularly characteristic; it does not appear in any other affection of the alimentary canal, and seems to be peculiar to cholera.

In comparatively few cases did he find the mucous membrane little changed; it looked swollen and less transparent in the upper layers, the solitary follicles and Peyer's patches were more prominent, the whole of the mucous membrane was of a light rose color, but in no case was there capillary bleeding.

In those cases which constitute the third class the contents of the bowels were colorless—not always like rice-water, but more like water which had been mixed with flour. Only a few cases came to his notice where the contents of the bowel were a watery mucus; the reddened edges surrounding Peyer's patches contained the most of the comma bacilli. All the animals which died after being injected with the virus presented the same symptoms and the same post-mortem appearances. Numerous experiments to this effect have recently been made by Koch, Klob, Nicati and Rietsch, Cautani, and others, and all to the same effect. In addition to the foregoing, I may state that the spleen in cholera cases, and in animals which died after being injected with the cholera bacillus of Koch, has always been found atrophied. It seems that the spleen of animals inoculated with the bacterium of Emmerich was found to be the reverse. In my opinion, all the experiments made upon animals must be accepted with caution as regards their bearing upon the cholera-germ question, because no cases are on record in which an animal ever has taken the cholera during any of the great epidemics in India and in Europe. They seem to enjoy an immunity from this disease, and whether we are able to produce it artificially or not is a question not yet solved to my satisfaction.

After this digression, I beg leave to mention one prophylactic which enjoys a reputation with some medical men up to the present time. It is the sulphate of copper, to be taken daily in very minute doses, during the whole course of an epidemic. The French particularly seem to have been impressed with this belief, and Burq, the father of metallotherapy, recommended it in 1857. French medical papers also quoted instances where large bodies of troops marched through cholera districts and enjoyed immunity from the disease, which was explained by the fact that they had been constantly dosed with the copper during the time they traveled through the infected locality. Dr. Garrigues, formerly of this city, stated to me that he attended a hospital with six hundred cholera patients, during the year 1864, at Copenhagen; that he took daily small doses of the copper, and did not get the cholera, but, as he remarked, other physicians in the same hospital, who also did not get the cholera, did not take the copper.

Gentlemen, I think the best prophylactic will be to avoid everything that tends to derange our digestive organs, and which may give rise to an intestinal or gastric catarrh. The healthy gastric juice will certainly kill the cholera germ; but an alkaline condition of the contents of the stomach will be the means of its passing into the intestinal canal, and then the mischief begins. I would, perhaps, recommend taking small quantities of hydrochloric acid every time we drink water. I should certainly prefer distilled or, at least, boiled water to the ordinary drinking-water. Although the bacillus can not live longer than two days and can not reproduce itself in pure water, the ordinary drinking-water may contain enough of the germ to infect us. The same with milk; it should never be used unless it has been boiled first; then milk in particular forms a good nutritive medium for the microbe.

In the rooms of the sick I would strictly enforce the rule that nobody should be allowed to eat or drink except the patient, and I would urge upon the attendants to wash their hands with a solution of bichloride before taking food. I would not trust to any other disinfectants in the rooms of the sick, unless later researches should give us practical proof that some of the articles of commerce now in the market, and highly extolled as disinfectants, will stand the scientific test against cholera germs. It seems that all acids are not destructive to the cholera germ, as is proved by the fact that it will grow upon freshly cut potatoes, and such a fresh cut has an acid reaction. For this reason I would advise to abstain from the use of fruits, apples in particular, because, besides that they have the faculty of rendering the contents of the stomach alkaline, they may also be the direct means of introducing the bacillus into the stomach. In using disinfectants we should strictly avoid those which retard putrefaction, for it has been amply proved that the bacillus of putrefaction is the deadliest enemy of the comma bacillus, and that wherever the former appears the latter disappears. To put sulphate of iron into a cesspool containing excrements of human beings during a cholera epidemic would prepare a good nutritive element for the germ. I would like to call the special attention of our Board of Health to the cesspools of our public resorts, particularly to those of Coney Island. If no proper care is exercised in disinfecting the same, they may be the cause of much suffering. Bichloride in liberal quantities, often applied, will be the only means, in my opinion. Not those means which only deodorize come into consideration in this momentous question, but those disinfectants which kill the germs of the

disease. The best of all means of killing the cholera bacillus is dry heat. If it is subjected to a drying process, it will die within a few hours. For this reason I mentioned before that I did not think the importation of rags from Europe could import the disease also, because all rags, before they are shipped for commerce, are subjected to a drying process. For the reason that dry heat kills the germ, I would recommend stopping the sprinkling of the streets during an epidemic of cholera, and I would also recommend that all the bed-clothing of cholera patients, and all the personal wearing apparel used during their illness, be subjected to a process of dry heat. If all the excrements could be destroyed by fire, it would be better still; but, as such a process would be difficult or impossible to accomplish, let us boil, at least, the clothes in a solution of bichloride, and then subject them to a process of drying in a hot stove, and, if they burn, it will be all the better. No wet clothing of cholera patients should be allowed to hang out in the yards or upon the roofs of houses to dry, there is such a possibility of a strong draught of air taking up the germ and carrying it to a soil where it may grow and increase. Gentlemen, you will remember the appropriate remarks made by the medical officer of the navy who visited our last meeting. You will remember that he told us that during a time when cholera was raging in India a United States man-of-war was lying in the Ganges in midstream, and none of the officers or crew took the cholera. Why did that happen? First, the proverbial cleanliness on board of a United States man-of-war, and, second—and may be, perhaps, first—because they drank only distilled water.

Although I told you that the comma bacillus could live only a few hours in water, and did not multiply there, it may grow upon the soil of the banks of a river, provided the soil happens to have some of the elements necessary for its reproduction. The stream of water may carry the germ along, and by that means become the cause of the disease —one reason more why we should drink only distilled or boiled water during those times, and why we should not sprinkle the streets. I beg leave to mention that Dr. Koch spoke to the Medical Society of Marseilles, and stated that, in his opinion, chloride of lime must not be relied upon as a means for disinfection. He advises keeping a five-per-cent. solution of carbolic acid in all vessels used in the room of a cholera patient. The best means of destroying the germ he considers hot steam, which must be used with an apparatus from which a jet of steam issues of a temperature of 100° C. Such a system may well be carried out in hospitals, etc., but in private dwellings, tenement-houses, etc., it will be impracticable, and I think boiling with a strong solution of bichloride, and afterward drying in a hot stove, will answer our purpose in private practice. The solution of sublimate which he recommends as wash-water for the hands of nurses and physicians who attend cholera patients should be of the strength of 1 to 1,000. Koch also urges to avoid drinking water unless it has been previously boiled, and he himself, during his stay at Marseilles, drank only mineral waters, and always washed his hands in a solution of sublimate before he took his meals. He strongly urges the washing of all cooking utensils, glasses, etc., with boiling water, and is of the opinion that, although beer in all probability does not contain the microbes, the water in which the glasses have been washed may do so, and thus cause infection. Gentlemen, I am of the opinion that our system of sewerage, our water supplies, etc., and the general sanitary condition of this city, thanks to the efforts of the Board of Health, are such that we may consider ourselves well prepared to meet the enemy if he attempts an invasion.

We hear of unclean streets, and in some parts of the city an improvement would be desirable, but, on the whole, we may compare well with such cities as Naples, Toulon, or Marseilles. Although it may be comfortable to contemplate this condition of affairs, vigilance in sanitary matters must not cease, and we, as physicians, should be willing to lend a helping hand to the efforts of the Board of Health to suppress an epidemic by reporting every suspected case as soon as it occurs. I contend that private interest must not be taken into consideration as long as the public welfare is at stake.

I have not mentioned in this paper the report of the English commission which was sent to India to investigate the cholera. The exact words which Dr. Klein used in his report, March 24th, before the Royal Medical and Chirurgical Society of London, copied from the London "Lancet" into the "Deutsche medicinische Wochenschrift," April 16, 1885, are the following: "Comma bacilli of various species have been discovered in other diseases of the alimentary canal, in the fluid of the mouth of normal persons (Lewis), and in old cheese (Deneke). The comma bacilli found by Finkler and Prior in cholera nostras differ in mode of growth from Koch's comma bacilli of cholera; so do those found in diarrhœa due to other causes; but those of the fluid of the mouth are identical with Koch's comma bacilli in *many* respects."

He admits, consequently, that they are not identical in *all* respects, and I may refer you to my former remarks that Dr. Lewis's bacilli do not grow upon alkaline nutritive gelatin. I would recommend to all those of you gentlemen who wish to be informed upon the subject of the cholera bacillus to read the reports to the Scientific Grants Committee of the British Medical Association, by W. Watson Cheyne, Assistant Surgeon to King's College Hospital, etc., and Research Scholar of the British Medical Association, as published in the "British Medical Journal." One of the articles published in the "Journal" of May 2, 1882, I have seen through the kindness of Dr. Hunt, and I found it to be such a lucid and true *exposé* of Koch's discoveries that I beg leave to mention it here. It gives all the illustrations, partly after Koch, and in a great measure after Mr. Cheyne's own investigations, and mentions also the later highly interesting researches of a Mr. E. M. Nelson in reference to the discovery of the flagella of the bacillus, before unknown to me. I would not have mentioned Dr. Klein's report in this paper, because I considered the matter as settled, had not an allusion to it been made at our last meeting, and if the president of the Medical and Chirurgical Faculty of Maryland, at the annual session, May 12th, as reported by

the "Medical Record," May 16th, had not stated in his opening address, "Origin and Diffusion of Cholera," that he "did not consider the parasitic origin of the disease proved, because Koch had not succeeded in producing the disease by injecting the comma bacilli, and Lewis had demonstrated the presence of bacilli in the human system under other circumstances." But not alone Koch, but Klob, Rietsch, Nicati, and others have successfully injected the comma bacillus into the intestines of animals, as already stated before, and Lewis's bacillus is certainly not identical with Koch's. Gentlemen, if a physician has a suspected case of kidney disease, he is expected to test the urine for albumin, and examine into the percentage of urea and look for casts, etc.; but, when it is necessary to make a quantitative analysis of the urine, he will be obliged to get a specialist to attend to the matter; for, even if he has the necessary knowledge and apparatus to do so, he has not the time. If a hospital surgeon removes a tumor from a patient he turns the specimen over to a pathologist for microscopical examination, and I think it will be the same with the examinations of the excrements of suspected cholera cases. We, as practical physicians, will be able to make the primary examinations by cultivation and with the microscope; but when it comes to further scientific researches into the matter, there our duty ends, and also our ability. A constant, untiring observation, together with the minutest attention to details, is necessary to carry out the investigations, and those of us who undertake to work further upon this field, with the hope of adding something new to the general knowledge, will be sorry to find that they worked in vain because they have no time for such researches. We have to content ourselves with utilizing the discoveries made by those who make it their sole study. If the German Government, however, thinks the matter of sufficient practical importance to detail by turns all the medical officers of the army to take a course in the laboratories of the board of health at Berlin, to enable the army physicians to make the necessary investigations for diagnostic purposes, I think it will not be out of the way if I herewith respectfully suggest that our Board of Health detail one of its members to take a course at the lately established laboratory of the Bellevue Hospital Medical College, for the purpose of familiarizing himself with the technical methods of making such investigations, and if, with a little financial aid from the city, the Board of Health could afterward establish a laboratory for biological researches, it would materially further rational sanitary purposes.

RIGGS'S DISEASE.

By G. A. MILLS.

At a meeting of the Connecticut Valley Dental Association, about eighteen years ago, at Northampton, Mass., John M. Riggs, M. D., of Hartford, Conn., was invited to make a proclamation (associated with a clinic) of his views concerning a diseased condition of the gums and the sockets of the teeth which often causes the loosening and falling out of the same. Up to this time nothing had appeared in the literature of dentistry except that which classed this disorder among the incurables, and it was spoken of as the result of senility; hence the common remark among people, "My father's and mother's teeth all dropped out, and it is only a matter of time with me." The removal of tartar as an external deposit upon the teeth was classed simply as an operation of scaling. This operation only recognized the foreign matter that could be seen. Dr. Riggs, in announcing his original views—while he gave it as his opinion that the deposits of tartar were the cause of the disorder under consideration—stated that his observation and experience matured the knowledge that there was a decided progressive inflammation existing under the gums and wasting both the hard and soft tissues, so that their attachments with the roots were gradually being destroyed. His knowledge of surgical principles suggested a practical application to these diseased localities, and he proceeded to the removal of all foreign substances from the roots of teeth, and the trimming of the necrosed edge of the alveolus to the life-line, leaving nature to restore to a normal condition. Dr. Riggs's view naturally excited a variety of comment—some expressing disbelief, and others accepting his novel ideas and statements. Not a few denied the existence of a necrosed edge of the alveolus. Dr. Riggs had devised a set of instruments well adapted for the treatment of this disorder—and these were unique and new, yet there was an effort on the part of a very few to dispute his claim to this invention; this did not prove a success. This body (the Connecticut Valley Dental Association) subsequently passed a resolution giving credit to Dr. Riggs for originality relative to the new pathology of the disorder now termed Riggs's disease, and so named at about that time in honor of Dr. Riggs. I have previously remarked that nothing of the doctor's views had ever been published so far as known. But—having become personally much interested in this disease, and in the discussion of it, and also finding my position regarding it misunderstood by several dentists—I was led to prepare a series of articles (six), which were published in the "Dental Cosmos" during the years 1876 and 1877, under the title of "What I know about Riggs's Disease," in one of which articles I challenged the record of views corresponding to Dr. Riggs's. Since then not a word has come from any source to show that he is antedated in the matter. I may add that a confirmation of his views and their acceptance by many members of the dental profession have gradually taken place. I am glad to say that to-day it is the most prominent subject for consideration before dentists generally. Only a limited number, however, have come to a correct understanding of what is required and how to meet the requirements. These few are demonstrating a successful treatment of the disorder. At this point of my article it seems advisable to introduce a feature which I shall elaborate later on; it is in reference to the technical term by which this disorder is now known—viz., *pericementitis*, substituted for the term well known by medical men—dental periostitis—meaning inflammation of the dental periosteum. This term (pericementitis) originated in the laboratory of Charles Heitzman, M. D., of New York city, during the late investigations made there by dentists under his instruction. The general subject of perice-

mentitis it is not my design to discuss here, but it is necessary to make the distinction clear between Riggs's disease and general pericementitis. Riggs's disease is a peculiar phase of pericementitis; it may exist to the final loss of all the teeth, without a sign of any other phase of this disorder.

As the nature of this disease is so plainly embodied in my brief history of the matter which includes its pathology, it would seem that my readers need not be ignorant of its main features; therefore I pass to consider the diagnosis.

To diagnosticate an incipient case, or first manifestation, as it is often seen in the mouths of children (even at a very early age): The simplest form of the disease may often be seen at the peripheral part of the festoon of the gum-tissue indicated by a congested appearance; by lifting this gum with a delicate instrument, there will be seen a little seed-like granule of calcific substance. Another case might show a deep red and raw-looking, elongated appearance of the gum-tissue about the necks of the teeth, and with or without any deposit; there may be also a looseness of the gum about the teeth, which causes quite a pocket. This latter condition is often a sequela of exanthematous disorders. The gums are often extremely sensitive to the touch. In the various cases we find general congestion, easy hæmorrhage, pale and bloodless gums, a decidedly anæmic and frequently pimpled surface of the gums—the latter appearance in adults. Not uncommonly a first warning to the patient (adult) will be pain or tenderness about the tooth or teeth, and an examination will not reveal any decay, death of pulp (commonly called nerve), or evidence of inflammation of pulp. This is what I shall term a subtle manifestation, for it has been believed there could be no inflammation of the dental membrane without a disturbance of the pulp. This is now proved to be untrue, for abscesses do occur while the pulp remains normal. In a large proportion of cases there will be, on light pressure, a flow of pus from under the gums, and oftentimes it is a copious discharge. This may be general, or it may be confined to a single tooth. Looseness of one or more of the teeth may be observed; also malposition, and this commonly after an occluding tooth is lost. I have given in detail enough of the manifestations to lead one even superficially familiar with unhealthy conditions to the diagnosis. It will be observed that I have omitted other conditions of disease that are manifested in the mouth, associated with the teeth and allied structures—viz.: syphilis, salivation, and scurvy. While in some instances these may be separated from the disorder in question, yet they are sometimes complications. I will mention another marked diagnostic feature associated always with an active stage of the disorder, and that is the odor which is distinctly noticeable to one familiar with Riggs's disease. There are other local manifestations that are, without doubt, largely influenced by the disease, but are commonly classed as expressions of constitutional debility, and still they may be wholly the result of the disorder under definition. This is proved by the arresting of the disease when the disabilities referred to are removed. Recession of gum-tissue is often seen, and no apparent inflammatory condition. While this is a peculiar phase, I maintain it is the same disorder. My term for it is atrophy of the gum-tissue—erosion of the tooth-structure, causing grooves across and around the necks of the teeth, not infrequently taking a serpentine direction. This also is a manifestation of the same disorder, as it is arrested by the treatment which will now be described.

Treatment.—As the nature of the disorder has proved to be novel, so will the treatment appear, as Dr. Riggs was the inventor of a set of instruments with which to perform the operations required in treating the disease. Each one is six inches in length, including the handle, which is of ebony and steel, octagonal and tapered; the blades are seven eighths of an inch long, bent at an obtuse angle. The instruments are in two pairs, and there are two single ones. One pair has a knife edge and a safe edge; the other pair has the same, but these are reversed in their bevels—made so for the purpose of working at a different angle of the mouth, and from the operator instead of toward him. The single ones are double knife-edged, and differing in thickness of blade. Perhaps no better idea can be given of the general form of the blades than to say they resemble the half of a snipe's bill, the long, ovoid point being particularly adapted to ferreting out the intricate and deep-seated disordered parts of the hard and soft tissues about the roots of the teeth. In their dimensions they may seem ponderous to a novice, but in the hands of an expert no instrument can be more efficiently and delicately used. It must now be seen, by the description and location of Riggs's disease, that most of the operation is under the gum-tissue and out of sight, so that necessarily to know when the operation is complete at a given point can only be accomplished by an acquired and acute sense of touch. It may be said that the Riggs treatment has instituted a distinct and systematic mode of arresting the disease. Rightly understood and rightly practiced, I regard this treatment as the most efficient in dental surgery. The severity of the cases differs according to constitutional conditions, and, if the dentist is the doctor, he will know whether the patient can be wisely aided by constitutional treatment. The prognosis must be based upon the conditions as they appear in each case.

From an extensive experience within the last ten years in the treatment of a large number of cases, and the success attained, I am justified in saying that Riggs's disease can no longer be classed among the incurable ones.

It is perfectly plain that this disease is not confined to any one period in life. Under the age of forty I have had numerous cases in the most active stages of progress—so noticeable that there was almost spontaneous hæmorrhage of the gums, and such an excessive flow of pus that the service of napkins for absorbing was required in sleeping hours. These facts can be testified to by well-known physicians. As one impressed with the prevalence of Riggs's disease, and its destructive effect on the general health, I should be remiss in duty if I were silent, or neglected to call the earnest attention of medical men and the public to the grave facts, for they have had too little consideration. I would say emphatically that the most serious complications may arise, and the worst septic conditions may be threatened

and encountered, from pure neglect. That one disorder not arrested calls others of a more serious nature into existence is a well-known fact among medical men.

Book Notices.

A Text-Book of the Principles of Physics. By Alfred Daniell, M. A., Lecturer on Physics in the School of Medicine, Edinburgh. London: Macmillan & Co., 1884. Pp. xx–653. [Price, $5.]

This book is intended to be used in the preliminary medical course. The author justly lays stress in the preface upon the importance of the study of physics, and the close relation between that branch and the department of experimental physiology. He states that it is his express purpose to avoid the introduction of "anything of the nature of an unsolved riddle" into his work. But the reader will find himself greatly in error if he regards this as an elementary treatise; a mere glance at the table of contents will assure him that he has not entered upon a course of light reading. The subject-matter is arranged in an ascending series. Beginning with introductory sections upon matter and its properties, we soon reach a solid chapter on "Kinematics," under which are included wave-motions and their demonstration by the aid of the higher mathematics. We prophesy that this will prove a tough morsel for the student, especially if he approaches it without a previous knowledge of the subject.

Under "Kinetics" are included the familiar problems of the lever, inclined plane, screw, and wedge, with a paragraph on friction. "Attraction and Potential" and "Gravitation and the Pendulum" form the subjects of Chapters VII and VIII. Chapters IX, X, XI, and XII include "Matter," "Solids," "Liquids," and "Gases." With Chapter XIII we begin an exhaustive consideration of "Heat," which is fully up to the latest theories. This is followed by "Sound," "Ether-waves" (as the author calls his chapter upon light), and a concluding dissertation upon "Electricity and Magnetism." An exhaustive bibliography and an excellent index conclude one of the most scholarly works on physics that we have ever had the pleasure of perusing. We regret that we can not give a more extended notice of the book, but this is hardly permissible in a strictly medical journal. The reader who is prepared to give his close attention to every page is advised to look it over for himself. A superficial reading is worse than useless, for, as we before stated, this is not light literature. The criticism which we venture to offer upon the volume as a whole is that it is entirely too advanced for the class for whom it is written. When we remember that the average medical student has not enjoyed a university education, we are compelled to believe that many of the pages of formulæ and mathematical demonstrations will be quite beyond his grasp. As for the "general reader," whom the author also includes among his audience, it will be a very intelligent general reader indeed who profits by some of the more abstruse paragraphs.

None of the familiar illustrations of physical apparatus have been introduced (we think unwisely), but their places have been supplied by numerous geometrical figures, often quite complicated. We do not wish to underrate the ability of our American medical students, but we must confess that few of them would take pleasure in physics with such a text-book. A little less of mathematics and a little more of the practical application of theories would be highly desirable.

The volume is a model of neatness and accuracy. The clear type, systematic arrangement—in fact, the *tout ensemble*—reflect great credit upon both author and publishers.

Resoconto clinico del comparto speciale per le malattie cutanee dell' Ospedale Maggiore di Milano, nel seiennio 1879–1884. Memoria del D. Ambrogio Bertarelli, medico aiutante. Milano: Tipografia Bortolotti di Dal Bono e C., 1885. Pp. vii–159.

As its title indicates, this book is a clinical report of the dermatological wards of the Ospedale Maggiore, of Milan, for the six years from 1879 to 1884 inclusive. We welcome it as another evidence of the intellectual activity of Italy, and as a voice from one of the largest hospitals in the world—one that was in operation before this country was discovered.

Unlike many hospital reports, it is not a mere collection of statistics, but resembles rather a series of clinical lectures upon selected and more or less uncommon cases that have come under the writer's notice. About thirty diseases of the skin are treated of, illustrated by cases, and discussed in regard to their ætiology, pathology, diagnosis, and treatment. The histories of many of the cases will well repay perusal, notably one of acute gangrene of the skin from softening of the brain. Much space is devoted to the consideration of eczema, lupus, and the parasitic diseases.

The author is an enthusiastic disciple of Hebra. His views are, nevertheless, not limited by the horizon of the Vienna school, but are catholic in scope. We notice that in his therapeutics he has given fair trial to the methods of the representative men of all nations, and his deductions from these trials enhance the value of the work. The book is of value as an exposition of the state of dermatology in Italy at the present time, and we can only regret that Dr. Bertarelli has stopped short of giving us a complete treatise upon the diseases of the skin as seen in his country.

BOOKS AND PAMPHLETS RECEIVED.

Gout, and its Relations to Diseases of the Liver and Kidneys. By Robson Roose, M. D., Fellow of the Royal College of Physicians in Edinburgh. London: H. K. Lewis, 1885. Pp. xii–158.

Manual of the Antiseptic Treatment of Wounds. For Students and Practitioners. By W. Watson Cheyne, M. B., F. R. C. S., Assistant Surgeon to King's College Hospital, etc. With Illustrations. New York: J. H. Vail & Co., 1885. Pp. xiii–151.

L'Année médicale (septième année), 1884. Résumé des progrès réalisés dans les sciences médicales. Publié sons la direction du Dr. Bourneville, Médicin de l'hospice de Bicêtre, Rédacteur en chef du "Progrès médical." Paris: E. Plon, Nourrit et Cie., 1885. Pp. viii–409.

Resoconto clinico del comparto speciale per le malattie cutanee dell' Ospedale Maggiore di Milano, nel seiennio 1879–1884. Memoria del D. Ambrogio Bertarelli, medico aiutante. Milano: Tipografia Bortolotti di Dal Bono e C., 1885. Pp. vii–159.

A Manual for Hospital Nurses and Others engaged in attending on the Sick. By Edward J. Domville, L. R. C. P. Lond., etc. Fifth Edition. Philadelphia: P. Blakiston, Son & Co., 1885. Pp. 96. [Price, 75*c.*]

The Pre-albuminuric Stage of Chronic Bright's Disease. By Charles W. Purdy, M. D., etc. Chicago: Clark & Longley, 1885. Pp. 35.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & Co. Edited by FRANK P. FOSTER, M. D.
NEW YORK, SATURDAY, JULY 25, 1885.

THE INTERNATIONAL MEDICAL CONGRESS.

So far as our information goes at the time we go to press, the week has been comparatively barren of striking incidents growing out of the International Medical Congress difficulty. We have no knowledge of further concerted action in the way of resolutions of disapproval and withdrawal, but individuals have in a number of instances publicly declared themselves in accord with the action taken in Philadelphia, Boston, Baltimore, and Washington, and at the same time expressed their intention not to take part in the Congress as at present sought to be organized. It is worthy of note that not a few of these gentlemen are residents of the West.

The inglorious part played by the New Orleans meeting of the American Medical Association continues to be the subject of comment. We have received a number of private communications approving of the position we took in our issue of the 11th inst., in which we explicitly fixed the responsibility for the present disgraceful state of affairs upon the association—not merely finding fault with the fortuitous indiscretion of the New Orleans meeting, but tracing the possibility of that action to the debased condition of the association itself. Many of our contemporaries are taking the same view of the matter, and some of them contain very pointed expressions. The "Medical Record" says that we have shown the association to be "a useless and mischief-making body." It precedes this statement with the remark that we were "at first a little non-committal, not to say strabismic," in our views; but this we take in the Pickwickian sense which is occasionally to be discerned between the "Record's" lines, and are content with its thorough approval of the position that it finally discovers us to hold.

The "Medical News" says: "The men who are engaged in original research, and who are best known as those who are contributing to the honor and dignity of American medicine by their writings and teachings, are not usually active in medical politics or in the supervision of their medical brethren, nor are they given to log-rolling and striving for office. For the past ten years these men have been becoming dissatisfied with the tone of the American Medical Association, and, while many of them have not formally severed their connection with it, they have nevertheless ceased to attend its meetings."

The "Maryland Medical Journal" uses the most forcible language to express its condemnation of the American Medical Association, as will be seen by its editorial of last week, which we reproduce elsewhere in this issue. The "Canada Medical and Surgical Journal" alludes to the withdrawals, and adds: "When we ask why they take this serious step, we learn that they have, in the first place, a deep distrust of the American Medical Association as an organization which could satisfactorily carry out such an undertaking."

Speaking of the general subject, the "Medical Times and Gazette," of London, says: "There is a very unfortunate discussion going on at present in professional circles in America, which, it is quite possible, may turn out disastrously for the International Medical Congress which it has been decided to hold at Washington in 1887. It will be remembered that a small Committee of the American Medical Association was nominated by the executive of the Copenhagen Congress, with full power to add to their number, and to act on behalf of their professional brethren. Carrying out their mission, they chose as colleagues twenty-eight leading American practitioners, especially selected on account of their standing in the profession, and drew up the programme which has already been published. Subsequently, when the Committee reported to the meeting of the American Medical Association at New Orleans, exception was taken to their proceedings on the plea that they had exceeded their powers, and had no commission to act on behalf of the association. The jealousies that had been roused among those who had been passed over in the co-optative selection were worked upon by two or three pushing wire-pullers, and, in the end, resolutions were passed, revising the work of the Committee, and substituting a Committee of thirty-eight men selected from the different States and Territories for those added to their number by the original Committee. At a subsequent meeting, the results of which we are daily expecting to hear, the subject was again to come under consideration, and we learn that it was the intention of all the leading practitioners in the States to withdraw from the Congress, if the decisions of the original Committee were not treated with more respect. We sincerely hope that the profession in America will strenuously support their recognized leaders; otherwise they will make an exhibition of themselves to the world, and, besides imperiling the future success of those international gatherings which have hitherto been conducted with so much harmony, will distinctly lower the respect in which the profession is held throughout the world."

MINOR PARAGRAPHS.

"DANIEL'S TEXAS MEDICAL JOURNAL."

"DANIEL'S TEXAS MEDICAL JOURNAL" is now, to use its own expression, launched. We lately took occasion to commend Dr. Daniel's undertaking, and he now reciprocates by mentioning this journal a number of times in his first issue. To be sure, much of what he puts forward as quotations from our columns never appeared in them, but we have grown quite accustomed to being misquoted and to having our meaning perverted. It seems that this journal was not the only one to notice Dr. Daniel's journal in advance of its appearance, for he quotes the following—and we envy the state of mind that enables him to reproduce it with apparent satisfaction—from the "Denver Medical Journal": "Dr. F. E. Daniel, of Austin, Texas, sends us the prospectus of 'Daniel's Texas Medical Journal.' To those of our readers who were lovers of the editorial writings of the much lamented Gaillard we commend Dr. Daniel as the coming

'Mephistopheles of medical journalism.' At least we will venture to so christen the baby." We wonder if Dr. Daniel has ever read Faust, and we wonder also if the "Denver Medical Journal" realized with what sort of character it coupled the name of a man who was utterly free from guile.

VIVISECTION IN ENGLAND.

We regret to learn that Mr. Lawson Tait has again thought fit to cast the weight of his influence publicly in aid of the anti-vivisection mania in England. We do not question his entire conscientiousness in the matter, and it is even conceivable that he might make a good argument in favor of the proposition "that vivisection is not only useless in solving riddles such as we have to deal with, but that it is absolutely misleading." A forcible argument could perhaps be made in support of that position, but certainly not one that would prove convincing to the present generation of medical men, who owe almost all that they possess of real physiological knowledge to the practice which Mr. Tait condemns.

THE PROPOSED TEACHING OF HYGIENE AT WEST POINT.

It seems to us that a most excellent suggestion has been made in the recent report of the Board of Visitors of the Military Academy, namely, that the officers of the medical corps on duty at the post should give lectures on hygiene to the senior class of cadets. Not only is it indisputable that a knowledge of the principles of hygiene by the line officers of the army is in the highest degree desirable, but it is also scarcely less certain that for the medical officers in question to devote a portion of their time to teaching those principles would be both agreeable and profitable to them as individuals and as officers. Moreover, in the course of a very few years the whole medical corps would find its routine duties much facilitated by the increased readiness with which officers in command of posts would grasp the purport and appreciate the importance of the hygienic measures recommended by the medical officers from time to time. We trust, therefore, that the board's suggestion will meet with favor at Washington.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 21, 1885:

DISEASES.	Week ending July 14.		Week ending July 21.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	1	0
Typhoid fever	9	2	10	2
Scarlet fever	31	9	40	14
Cerebro-spinal meningitis	4	3	4	3
Measles	55	10	48	8
Diphtheria	55	24	59	23
Small-pox	2	1	2	0

Small-pox is reported as prevailing in the town of Scotland, in Dakota, twenty-five cases having been discovered last Sunday.

Anthrax in Louisiana.—Anthrax is reported to be prevailing extensively among cattle in the region of New Iberia, La.

The International Sanitary Conference and the Disinfection of Rags.—One of the incidents in a controversy that has been going on for some months between certain sanitary officials and the importers of rags was the suggestion that a report of the proceedings of the recent International Sanitary Conference held in Rome, which appeared in a Philadelphia medical journal, contained an interpolation by the correspondent of the journal in question, in the following clause: "Disinfection of merchandise and of the mails is unnecessary (steam under pressure is the only reliable agent for the disinfection of rags—*les chiffons en gros*)." This suggestion having been urged in the "New York Times," the American delegate to the Conference, Dr. George M. Sternberg, of the army, wrote to that paper denying the truth of the charge and affirming the accuracy of the account given in the Philadelphia journal. The "Times" now returns to the matter and publishes the following remarkable statement: "A gentleman of this city, who is interested in the importation of paper stock, wrote to Dr. Koch, at Berlin, for definite information on this point, and yesterday he received a cablegram stating that no such words as those quoted in parentheses appear in the report of the committee."

The American Laryngological Association.—At the recent annual meeting, held in Detroit, Dr. Wilhelm Meyer, the distinguished professor of laryngology in the University of Copenhagen, and president of the combined laryngological and otological sections of the last International Medical Congress, was unanimously elected a corresponding fellow of the association. Dr. H. Clinton McSherry, of Baltimore, and Dr. Charles H. Knight, of New York, were elected to active fellowship.

Professor Tyndall's Gift to American Colleges.—The "British Medical Journal" states that the proceeds of Professor Tyndall's lectures in the United States in 1872, which, with the accumulated interest, now amount to $32,400, are to be divided equally between Columbia College, Harvard University, and the University of Pennsylvania.

The Medico-Chirurgical College of Philadelphia.—We learn that Dr. F. Le Sieur Weir has severed his connection with the college.

The Death of Dr. Thomas E. Burtsell, of New York, took place on Thursday of last week. The deceased was a graduate of the Medical Department of the University of the City of New York, in the class of 1844.

The Death of Surgeon Joseph H. Bill, of the Army, took place in Yonkers on Tuesday last. He was a native of Pennsylvania, and was appointed first lieutenant and assistant surgeon April 13, 1860. March 13, 1865, he received the brevet ranks of major and of lieutenant-colonel for faithful and meritorious service during the war. April 13, 1865, he was commissioned captain and assistant surgeon, and July 28, 1866, major and surgeon. His death is said to have been due to Bright's disease.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 12, 1885, to July 18, 1885:*

Vollum, E. P., Lieutenant Colonel and Surgeon. To be relieved from duty in Department of the East on the expiration of his present leave of absence and to report to commanding general, Department of the Platte, for assignment to duty as attending surgeon at the headquarters of that department. S. O. 159, A. G. O., July 14, 1885.

Middleton, J. V. D., Major and Surgeon. Leave of absence extended fifteen days. S. O. 159, A. G. O., July 14, 1885.

Brown, J. M., Major and Surgeon, Captain Clarence Ewen, Assistant Surgeon, Captain A. W. Taylor, Assistant Surgeon, and First Lieutenant W. C. Borden, Assistant Surgeon. Ordered to prepare for field service. S. O. 64, Department of the Platte, July 9, 1885.

GRAY, W. W., Captain and Assistant Surgeon. Relieved from duty at Fort Barrancas, Fla., and ordered for duty at Fort Columbus, New York Harbor. S. O. 147, Department of the East, July 13, 1885.

EVERTS, EDWARD, First Lieutenant and Assistant Surgeon. Ordered for duty as Post Surgeon, Fort McDermit, Nevada. S. O. 68, Department of California, July 11, 1885.

POLHEMUS, A. S., First Lieutenant and Assistant Surgeon. Ordered for duty as Post Surgeon, Benicia Barracks, California. S. O. 68, Department of California, July 11, 1885.

WINNE, C. K., Captain and Assistant Surgeon. Ordered for duty at Benicia Arsenal, California. S. O. 68, Department of California, July 11, 1885.

EDIE, G. L., and C. S. BLACK, First Lieutenants and Assistant Surgeons. Ordered for duty with troops en route to Department of Missouri. S. O. 78, Department of Texas, July 10, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the week ending July 18, 1885.*

OWENS, THOMAS, Assistant Surgeon. Granted sick leave for one month. July 14, 1885.

Society Meetings for the Coming Week:

MONDAY, *July 27th:* Boston Society for Medical Improvement.

TUESDAY, *July 28th:* Medical Society of the County of Putnam, N. Y. (annual).

WEDNESDAY, *July 29th:* Auburn, N. Y., City Medical Association; Gloucester County, N. J., Medical Society (quarterly); Berkshire District (Pittsfield) and Middlesex North District (Lowell), Mass., Medical Societies.

THURSDAY, *July 30th:* Cumberland County, Me., Medical Society (Portland).

Proceedings of Societies.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-first Annual Session, held at the Pequot House, New London, Conn., Wednesday and Thursday, July 15 and 16, 1885.

Wednesday's Proceedings.—Morning Session.

THE meeting was called to order by the president, Dr. WILLIAM F. NORRIS, of Philadelphia.

Operation for the Removal of a Dislocated Crystalline Lens.—Dr. C. R. AGNEW, of New York, related the steps of the operation as follows: The pupil was dilated, and the patient was then etherized and cocaine was applied. The eye was secured with fixation forceps. An instrument resembling a two-pronged fork, which was termed a bident, was introduced into the vitreous chamber behind the dislocated lens, pressing it forward. Section was then made and the lens removed. The eye was dressed with absorbent cotton and a black silk bandage. Antiseptic solutions were used, and a four-per-cent. solution of cocaine was applied twice a day. The eye recovered without any unpleasant symptoms. The speaker did not claim that all dislocated lenses should be removed, but this instrument facilitated the operation when it was required.

Extraction of a Dislocated Lens.—Dr. DAVID WEBSTER, of New York, reported the case of a patient who received a blow on the right eye. This was immediately followed by loss of sight. Examination showed that the lens was dislocated. No treatment was recommended at that time. Some months later, pain suddenly appeared in the injured eye. The lens was found to be cataractous and incarcerated in the pupil. Cocaine was applied, but did not relieve the pain. Atropine relieved the pain. Later the lens became loose and was found in the vitreous. The tension was normal. It was decided to remove the lens. The bident was passed back of the lens, pressing it forward. The incision in the cornea was then made and the lens removed with a spoon. The eye was dressed with absorbent cotton, and recovered without complication.

Dr. H. KNAPP thought that in these cases there was not much difficulty in removing the lens, which could often be accomplished with the loss of very little vitreous, but the danger came in afterward from inflammatory complications; and where the sight was lost he thought it better to enucleate the eye at once and thus lessen the dangers of inflammation.

Dr. WILLIAMS, of Cincinnati, agreed with Dr. Knapp that enucleation was the best procedure.

Dr. AGNEW thought that the bident might also be useful in the removal of foreign bodies from the interior of the eye. He did not acquiesce in the view that enucleation was a simple operation. He regarded it as a serious mutilation.

Dr. C. H. WILLIAMS, of Boston, thought that there was another alternative than those mentioned, and that was eviseration of the eye, and closure of the anterior opening with sutures. He thought this better than enucleation, and it gave a better stump for the artificial eye.

Extraction of the Lens in its Capsule.—Dr. D. B. ST. JOHN ROOSA, of New York, said that for the past three years he had been in the habit of removing the lens in its capsule, in a large proportion of cases without iridectomy. The section was made as usual, but large. After puncture and counter-puncture were made, the knife was turned on its back so that it rested on the iris. It was then moved up and down two or three times until the lens was seen to move; then the section was completed, and the lens could usually be removed without loss of vitreous. Sometimes after the operation the iris was rolled under, but in many cases the pupil was circular. Dr. Roosa had performed the operation between thirty and forty times, and was satisfied with his success.

Sub-conjunctival Luxation of the Lens.—Dr. GEORGE C. HARLAN, of Philadelphia, reported two cases. In the first case no operation was recommended, as vision was good. In the second case the lens was removed. In those exceptional cases in which vision remained, the operator should think twice before resorting to removal.

Dislocation of the Lens under Tenon's Capsule.—Dr. O. F. WADSWORTH, of Boston, reported a case in which the eye had been injured two weeks before the patient came under observation. There was loss of sight, pain about the eye and irritation of the other eye, the cornea was hazy, and there was blood in the anterior chamber. The eye was enucleated, and it was found that the lens was beneath Tenon's capsule, and that it was held in this position by inflammatory tissue.

The Treatment of Purulent Conjunctivitis.—Dr. J. A. ANDREWS, of New York, read a paper on this subject in which he said that the treatment was based upon the belief that the contagious element was of the micrococcus variety. He related a case in which he had secured an inoculation of the seventh generation of a pure cultivation of a gonococcus. This was the first case inoculated with the gonococcus. He exhibited an instrument which he had devised to wash out the conjunctival *cul-de-sac*. It consisted of an eye speculum with hollow arms through which fluid might be passed. He had found bichloride-of-mercury solution (1 to 10,000) serviceable, but apt to irritate. A six-per-cent. solution of boric acid was also found efficient.

A two-per-cent. solution of carbolic acid was useful, as it inhibited the movements of the white corpuscles. Irrigation should be maintained for ten minutes in order to remove all secretion. Nitrate-of-silver solution (two to twelve per cent.) was then used, and an antiseptic dressing was next applied. This consisted of vaseline and boric acid or carbolic acid; but he laid especial stress upon the importance of maintaining irrigation of the conjunctiva by means of the instrument referred to.

Abscess of both Frontal Sinuses.—Dr. Charles S. Bull, of New York, related a case in which the patient had been hit on the forehead fourteen years previously with a piece of wood. This produced a fracture of both nasal bones and deviation of the septum. In seven weeks the wound had closed. Ten years after the accident a swelling was noted at the upper inner angle of the right orbit which could be made to disappear by pressure. There was complete ptosis. An incision was made into the swelling just beneath the orbital margin and a large quantity of pus escaped (two or three ounces). The cavity was washed with a five-per-cent. solution of carbolic acid. The septum between the two frontal sinuses was absorbed and both sinuses were converted into large cavities. The entire ethmoid bone was an immense cavity, the bony suture being absorbed. A number of osteophites were removed and a drainage-tube was introduced. The patient was discharged six weeks after the operation and recovered completely. The ptosis disappeared and the eye was restored to the normal plane.

Dr. Knapp recommended the substitution of a silver tube for the rubber drainage-tube usually employed.

Bony Tumor of the Orbit.—Dr. B. E. Fryer, of Kansas City, Mo., related the case of a boy six years of age who came under observation in April, 1885. There was swelling of the left orbit, which included the whole line of the superciliary ridge. It was quite hard. The boy had been struck with a piece of wood. It was decided to remove the tumor. This was done, and, on examination, it proved to be a cyst within which was a small piece of wood. This was inclosed in bone on all sides. The edges of the wound were brought together and healing resulted without complication.

Sarcoma of the Orbit in a Child.—Dr. W. H. Carmalt, of New Haven, Conn., reported the case of a child of ten years of age from whom he removed a small growth from the upper lid. Six weeks later the growth had returned. An exploratory operation was done, and it was found that the growth extended into the orbit, and that it was impossible to remove it entirely. It was therefore decided not to complete the operation. The child had since died, and the tumor proved to be a rapidly growing sarcoma. He thought that, if in young children the tumor appeared to be quickly recurrent and not easily isolated, no operative interference should be attempted.

Dr. Kipp, of Newark, thought that in many cases these tumors of the orbit were not primary, but secondary, and that the primary tumor might be in such a position as not to attract attention.

Dr. Harlan, of Philadelphia, reported several instances of inflammatory exudations in the orbit simulating tumors, and illustrating the importance of exercising great care in diagnosis.

Some of the Results obtained in the Compilation of 1,000 Cases of Refraction.—Dr. E. E. Holt, of Portland, Me., had been in the habit of recording all the measurements connected with the prescribing of glasses. As a result, he had found, in 1,000 cases thus recorded, the average distance between the centers of the pupils of the human eye to be about 60 mm. The average of other measurements was given, and the importance of the physician determining and designating them, and then seeing that they were carried out, was dwelt upon.

Rapidly Progressive Myopia checked by Section of the External Rectus.—Dr. Harlan related the case of a boy of sixteen in whom myopia was progressing rapidly. The external rectus was divided seven years ago. The internal rectus was also excised by the use of prisms. Since then there has been no increase of the myopia.

Progressive Astigmatism.—Dr. Samuel Theobald, of Baltimore, related three cases of this affection.

Afternoon Session.

Hypermetropic Refraction passing into Myopic Refraction.—Dr. S. D. Risley, of Philadelphia, had on previous occasions called attention to five cases of a similar kind, and the object of his paper was simply to report six additional cases seen within the past year.

The Demonstration of Refraction and Accommodation.—An apparatus for this purpose was exhibited by Dr. Lucien Howe, of Buffalo, N. Y. It consisted of two bands of thin metal bent in such a manner as to represent the outlines of a double convex lens, and passing through it were two jointed rods representing the rays of light ordinarily figured as passing through such a lens and joining at its focus. The flexible bands were attached to each other above and below, so that, by approaching or separating the sides, they could be made to show less or greater convexity. The rods representing the rays of light were jointed near the center in such a way that while the two halves could be placed in such a direction as to show the light as entering parallel to the axis of the lens, the other two portions could be bent to a point to show the convergence of rays at the focus. By alteration in the position of these rods, and also in the forms of the bands representing the lens, all the different variations of the laws of refraction and the changes in accommodation could be demonstrated to a class.

Two Cases of Unilateral Temporal Hemianopsia.—Dr. C. S. Bull read a paper with this title. [It will be published in full in a future number of the journal.]

Penetration of the Eyeball with Scissors in the Operation for Strabismus.—Dr. H. Derby, of Boston, reported two cases, the first of which was that of a young man on whom an operation for strabismus had been attempted. The surgeon inadvertently picked up a pair of sharp-pointed scissors. The point of the scissors suddenly penetrated the eyeball, and a portion of vitreous, equal in size to a cherry-stone, escaped. The operation was abandoned, and Dr. Derby was called to see the case. The eye was bandaged and the patient put to bed. Several attacks of inflammation supervened, but the patient was discharged on the forty-first day with $V = \frac{7}{10}$.

In the second case the scissors also entered the sclerotic, but, after a somewhat tedious convalescence, the wound was found closed on the twenty-first day with vision as good as before the operation.

Dr. Knapp stated that he had done three thousand squint operations, and in three cases he had punctured the sclerotic. He, however, completed the division of the muscle, and the patients recovered as readily as from an uncomplicated operation.

Dr. Mittendorf thought that in case the accident happened the division of the muscle should be completed.

Dr. E. Williams reported a case in which he had punctured the eye. The patient recovered without difficulty.

Strabismus; its Correction when Excessive and in High Degrees of Amblyopia.—Dr. E. E. Holt read a paper with this title, in which he said that he had employed advancement of the weakened, attenuated muscle in connection with tenotomy in certain cases of squint, and after tenotomy alone had failed to correct the deviation. He also exhibited an apparatus that he had devised for showing the associated and accommoda-

tive movements of the eyes and the effects of tenotomy and advancement of the muscle in correcting squint.

Dr. KIPP had at one time employed advancement, but he had given it up because it was difficult to graduate the result.

The Treatment of Strabismus Internus.—Dr. W. W. SEELY, of Cincinnati, read a paper with this title, and from which he made the following deductions: 1. That, with our present knowledge, routine operative interference is wrong. 2. That to thoroughly correct the deviation in young children by operative interference is extremely liable to subject them in after life to insufficiency or external squint. 3. That a later period of life, if anything, favors better results from operative interference.

Dr. KNAPP considered advancement a dangerous operation. He had always been able to correct the deviation by two or three tenotomies, and, if necessary, by stitching the eye to the commisure.

Dr. THEOBALD indorsed Dr. Knapp's views in reference to advancement. He was surprised at the conclusions of Dr. Seely. Squint operations in his hands had been very satisfactory. If postponed, they were likely to prove unsatisfactory on account of the amblyopia which was liable to develop.

Dr. O. F. WADSWORTH had convinced himself that amblyopia from squint did not occur. The ability of the patient to use the vision which he had seemed to be lost by a continuance of the squint, but it might be recovered by practice.

Ectropion of Both Lids; Blepharoplasty by the Italian Method.—Dr. R. H. DERBY, of New York, reported a case in which the displacement of the lids was the result of cicatricial tissue from a severe and extensive burn of the face. The lids were loosened from their attachments, and the new lids were formed from flaps raised from the arm. The arm was bound to the head with water-glass plaster, and the pedicle was not divided until union had taken place.

Plastic Operations without Pedicles.—Dr. B. JOY JEFFRIES, of Boston, read a paper with this title, in which he suggested the use of the prepuce from the circumcision of Jewish children for operations about the eyes. He also suggested that in plastic operations the desired result might be obtained without the use of a flap by employing carbolized-oil dressings to retard healing.

(*To be concluded.*)

AMERICAN OTOLOGICAL SOCIETY.

Eighteenth Annual Meeting, held in New London, Conn., Tuesday, July 14, 1885.

The President, Dr. C. H. BURNETT, of Philadelphia, in the Chair.

Dr. CHARLES J. KIPP, of Newark, showed a copy of Retzius's work on the "Anatomy of the Organ of Hearing in Vertebrate Animals."

The PRESIDENT reported the deaths of two members during the year—Dr. John H. Dix, of Boston, and Dr. Edward T. Ely, of New York.

Inflammation of the Attic of the Tympanum.—Dr. SAMUEL SEXTON, of New York, read a paper in which he first referred to the importance of inflammation arising in the attic as compared with that arising in the atrium. The atticus tympanicus was described as that portion of the tympanum lying above a plane extending transversely from the prominence on the inner wall, formed by the external semicircular and facial canals, to the auditory plate on the outside. Beneath this plane lay the atrium tympanicum. Over the attic arches were the tegmen, which also covered the antrum, the petro-mastoid canal, a varying number of cellules, and the Eustachian tube. The attic communicated freely with the antrum by means of the petro-mastoid canal of Sappey. The mastoid antrum lay behind and to the outer side of the attic, in the spongy substance of the mastoid. It was usually larger than the attic, and, as a rule, extended downward among the cellules of the mastoid process, giving off frequently a small passage, communicating with the cellules overlying the external auditory meatus. The attic was divided below into two compartments, the inner being the larger, by the incus and malleus, the cord, ligaments, etc., which formed a partial antero-posterior partition. These compartments communicated freely with each other above, with the atrium below, with the Eustachian tube in front, and with the antrum behind. The outer compartment was wedge-shaped, larger above, and shut in below by the close approximation of the large ossicles to the auditory plate, except anteriorly and posteriorly, where two small openings allowed of drainage into the atrium below. The inner compartment also communicated with the atrium by an elliptical opening surrounded on the inner side by the facial canal and on the outer by the large ossicles, the cord, ligaments, etc. All these cavities were lined throughout with mucous membrane. Acute inflammation of the attic might result from catarrh of the head, the exanthemata, or the entrance of fluids propelled along the Eustachian tube in bathing or from the use of the nasal douche. Irritating fluids seemed always to be better borne in the lower than in the upper part of the tympanum. Inflammation of the attic might occur in connection with, or be independent of, inflammation of the atrium. It was the more serious from the fact that swelling of the mucous membrane clogged the outlets and prevented drainage. In such cases the membrana flaccida was red, the vascular turgescence extending above into the external auditory canal and sometimes downward about the short process of the mallet. Should the disease progress further, the inflammation might extend beneath the margo tympanicus of the auditory plate, and be followed by effusion of serum and blood, which pressed away the membrana flaccida and the integument of the canal, producing a bulging sac so great sometimes as to entirely conceal the membrana tympani, and it might entirely fill the canal and present at the lumen as a purplish tumor. Periostitis of the surrounding parts might occur and extend along the surfaces of the canal, and inflammation might spread to the atrium; but, so long as this did not occur and the membrana tympani was unaffected, there might be little deafness, though autophonia might be present. In nearly all these cases inflammation in some degree extended into the antrum and mastoid cellules, or those overlying the external auditory canal, or those situated in the tegmen. If the escape of secretions into the atrium or Eustachian tube was prevented, the case was more severe and extension to the cranial cavity more to be feared.

The proper treatment was to effect drainage and employ such constitutional remedies as tended to check the inflammation and prevent the formation of pus, such as aconite, calx sulphurata, etc. It was impossible to make an accurate differential diagnosis between the pains of pachymeningitis and the neuralgic pains of otitis media. The surgeon should therefore be cautious about trephining the mastoid where pain was the only symptom. After pachymeningitis had set in, it was manifestly useless to perform this operation.

Dr. D. B. ST. JOHN ROOSA, of New York, thought that the remedies mentioned, mercury and calcium sulphide, were not in common use in the way recommended by the author. He had used them without any favorable effect. A warm room, a good nurse, taking care of the bowels, and local measures were the most important. The internal treatment should be expectant. He would like Dr. Sexton to describe a case indicating the manner in which he would use these remedies.

Dr. SEXTON stated that the particular point of his paper was

in regard to the inflammation of the attic, and not the use of remedies. The moment there were symptoms of purulency he administered the calcium sulphide.

Dr. J. A. Andrews, of New York, referred to a case in which the inflammation was most intense in the upper part of the tympanic cavity, and a perforation was established between the mastoid antrum and the external auditory canal. There was a great deal of swelling of the external auditory canal. Examination under ether showed a fluctuating swelling in the superior-posterior part of the canal, which was incised, and considerable blood and pus escaped.

Dr. O. D. Pomeroy, of New York, asked if Dr. Sexton believed that mercury relieved the pain.

Dr. Sexton had never used it exclusively to relieve pain, and had not recommended it for that purpose. For the relief of pain he would recommend the use of aconite and pulsatilla, the latter especially.

Dr. C. R. Agnew, of New York, said that when there was acute otitis media it was desirable to cut it short as soon as possible. If a patient came to him with the symptoms of beginning otitis media he would give him fifteen grains of calomel and order a Turkish bath if that was accessible. With children there was always a certain amount of indefiniteness in the symptoms. He asked Dr. Sexton what he would do in a case of acute otitis media catarrhalis in an infant six months old.

Dr. Sexton would examine the history. If there was an accumulation he would let it out. In the majority of cases at this age the membrane had already ruptured when the case came under observation. If there was suppuration, he would give calcium sulphide. If there was simply catarrh, he would give mercury.

Dr. Kipp spoke of the value of inflation of the middle ear. This relieved the pain. Where there was protrusion in front of the membrane, incision gave relief.

Dr. Theobald, of Baltimore, had found the instillation of a warm solution of atropine of great service, a solution of the strength of four grains to the ounce. He had used pyrophosphate of sodium in fifteen-grain doses in inflammation of the middle ear with threatened mastoid implication, and was convinced that it was of real value.

Dr. C. J. Blake, of Boston, referred to a reduplication of the mucous membrane in the upper portion of the tympanic cavity, which he had found in fifteen or twenty per cent. of two hundred specimens examined. This served to separate the upper portion of the tympanic cavity from the lower. It became an important element in inflammation of this part, and might tend to retain secretions.

Dr. Sexton had used mercury and sulphide of calcium for the last ten years in many cases, and was convinced that they were beneficial in a certain number.

The Treatment of Chronic Otitis Media.—Dr. W. W. Seely, of Cincinnati, read a paper with this title, which closed with the following conclusions: 1. Only long observation (often lasting over months) in each case could determine whether treatment should be continuous (daily) or interrupted—*i. e.*, perhaps daily for a week, followed by an interruption of some weeks or months. 2. Only experience in each case could inform us whether treatment was to be entirely directed to the middle ear, or entirely to the naso-pharynx, or combined against both. 3. Only experience in each case could inform us whether injections into the cavitas tympani were called for. Under this head it was stated that direct medication, either of the middle ear or the naso-pharynx, as routine treatment, was unwise till simple inflation had failed. 4. Mechanical dilatation of the tubes was rarely necessary or advisable; only in extremely dry states of the tube was dilatation followed by much success. 5. Hearing-tests were not reliable, and hence patients with great deafness, great loss of bone conduction, etc., should not be sent away till the test by trial had been gone through with. 6. Simple inflation failing, the greatest attention should be given to the naso-pharynx, even though it was apparently in a fair condition. 7. Syringing, douching, and swabbing the naso-pharynx should be abandoned.

The Relations between Chronic Catarrhal Otitis Media and Chronic Rhinitis.—The President read a paper in which he stated that he had found a constant causal relation between chronic catarrh of the middle ear and chronic rhinitis and rhinopharyngitis. The latter was chiefly of the hypertrophic form. The atrophic form constituted about fourteen and a half per cent. The appearances of the membrana tympani in the first class were very diversified—so much so as to preclude a determination of the state of the middle ear and hearing from them alone. In the atrophic class, the symptoms presented by the membrana tympani were more uniform and consistent, and the surgeon was able to determine from them more precisely concerning the aural disease. Yet, on the whole, the appearances of the drum, taken by themselves, could not aid greatly in the diagnosis of chronic aural catarrh. Tinnitus aurium was, as a rule, more marked in the atrophic class than in the hypertrophic. There was also a greater patency of the Eustachian tube in the atrophic forms than in the hypertrophic. It was most relieved by treatment of the nares and naso-pharynx. The treatment in the first class should be by cleansing and astringent sprays, with applications of preparations of iodine never stronger than half-and-half. Nitrate of silver was not to be used at all in hypertrophic rhinitis. In the atrophic form, the treatment was cleansing, the removal of inspissations if they occurred, and the application of stimulant sprays, preferably of nitrate of silver, not stronger than four grains to the ounce of water. Where the hypertrophies had become dense and large, requiring surgical removal, the case should pass into the hands of the rhinologist. A word of caution was given in regard to the use of the galvanic cautery in the nares, since, like the nasal douche, it might lead to inflammation in the naso-pharynx and middle ear.

Dr. Agnew thought there was an anatomical objection to the use of salves, and that was the impossibility of applying them to the whole of the diseased surface by means of Bowman's probe. He was not prepared to accept the law that the nasal syringe should be abandoned. He thought more stress should have been laid on hygiene, which was the most important element in the treatment.

Dr. Roosa also considered that the principal and only benefit to be obtained in the majority of these cases was from proper hygiene; it was not necessary to continue examinations very long or repeat them very often to determine whether or not relief might be expected. If there was diminished bone conduction, it was useless to go on and treat the patient.

Dr. H. Knapp, of New York, had employed in his own person a salve of iodoform with vaseline with considerable advantage.

Dr. Seely had had more satisfaction from salves than from any other treatment. They remained longer in contact with the affected part than solutions, thus giving a more decided effect.

Afternoon Session.

Dr. Sexton presented a conversation tube for the aural instruction of deaf-mutes. By means of this tube the patient was able to hear his own voice and compare it with the voice of his teacher.

Professor Graham Bell called attention to the great number of children classed as deaf-mutes who, under proper education, could be made simply hard-hearing members of society.

A Case of Fatal Ear Disease beginning as a Circumscribed Inflammation of the External Auditory Canal.—Dr. Kipp read the history of the case of a married woman, aged twenty-eight years, who was first seen nine months before her death. Since a confinement, four months before, she had suffered occasionally with severe pain in and about the left ear. There were swelling and redness of the posterior upper wall of the external canal. There was no perforation and no otorrhœa. Under the use of leeches, instillations of morphine, and inflation of the middle ear, there was decided improvement in the course of a month, when she passed from under observation. Eight or nine months later the pain again appeared, shortly after a confinement. Examination of the ear showed great swelling of the external canal, but the tympanic membrane and the middle ear appeared to be normal, and there was no tenderness over the mastoid. The patient recovered from this attack, but the pain in the head continued, and she finally died. At the autopsy there was found evidence of intense inflammation over the entire extent of the arachnoid and pia mater. There was a collection of pus immediately over the posterior surface of the petrous portion of the temporal bone. Pus was also found on the pons Varolii. A small abscess was found in the anterior part of the left lobe of the cerebellum, near its junction with the pons. The mastoid cells were filled with pus. There was only a thin exudation in the middle ear.

The President reported a case similar in many respects, in which the patient died from what was diagnosticated as cerebral abscess, but no autopsy could be obtained.

Dr. E. E. Holt, of Portland, Me., reported the present condition of a patient from whom teratoid tumors had been removed two years ago, and in whom the disease had returned in one year.

The Local Use of Cocaine and Brucine in Diseases of the Ear.—The President read a paper in which he said that he had used the sulphate and the hydrochlorate of cocaine to produce anæsthesia in painful affections of the ear. Neither was efficient when the pain was due to inflammation of the dense tissues of the external auditory canal, nor when acute inflammation occurred in chronically thickened periosteal and mucous tissues in the tympanic cavity. A four-per-cent. solution of the hydrochlorate induced anæsthesia in congestion of the skin of the fundus of the auditory canal and in the membrana flaccida where the pain was not too intense and continuous. The solution was applied directly to the affected part, while the canal was illuminated by the head-mirror. The anæsthesia of the external auditory canal produced by cocaine was not profound enough to permit of painless incision into it. He had also used brucine in a five-per-cent. solution with success in producing local anæsthesia.

Does Cocaine Hydrochlorate, while relieving the Pain in Acute Otitis Media, prolong the Congestion?—Dr. Holt read a paper with this title. This question had occurred to him several times where he had used the remedy for the relief of pain in the middle ear. He was satisfied that, while cocaine relieved the pain, and for the time held the inflammation in check, yet, after the effect of the remedy passed off, the inflammation went on unaffected.

On the Desirability of adopting a Uniform Method of expressing the Results of testing the Acuteness of Hearing was the title of a paper read by Dr. Knapp, in which the following method of record was suggested:

H $= \frac{24}{24}$, normal hearing for a watch.

H $= \frac{20}{20}$, normal hearing for the whispered voice.

H $= \frac{20}{60}$, normal hearing for conversational speech.

H $= \frac{20}{\infty}$, whisper or speech heard, but not understood (qualitative perception of sound).

H 60′ = O, voice not heard at all.

H = O, complete deafness for all sounds.

H $= \frac{C}{24}$, a watch of 24″ hearing distance heard on contact with ear.

H $= \frac{Pr.}{24}$, a watch of 24″ hearing distance heard when pressed on ear.

H $= \frac{M}{24}$, a watch of 24″ hearing distance heard when applied to mastoid.

H $= \frac{T}{24}$, a watch of 24″ hearing distance heard when applied to temple.

H $= \frac{O}{24}$, a watch of 24″ hearing distance heard when applied to teeth.

H $= \frac{Gl.}{24}$, a watch of 24″ hearing distance heard when applied to forehead (*glabella*).

H $= \frac{V}{24}$, a watch of 24″ hearing distance heard when applied to vertex.

H $= \frac{Ub.}{24}$, a watch of 24″ hearing distance heard when applied anywhere (*ubique*).

To indicate that the watch was not heard at the places enumerated, the following were used: H $\frac{C}{24}$ = O, H $\frac{M}{24}$ = O, etc. H $\frac{Ub.}{24}$ = O would mean that bone-conduction for the watch was lost.

Presbykusis.—In a paper with this title, Dr. Roosa applied the term to the failure of hearing incident to old age and not dependent upon inflammatory affections. It came on after the age of forty or fifty years. Such persons heard badly in a noisy room. They heard the watch badly, but in a quiet room they could hear quite well. This was characteristic of the affection. In inflammatory troubles with the ear, the person often could hear pretty well in a noise, while in a quiet room he heard badly. These three symptoms went together: diminished bone-conduction, difficulty of hearing in a noise, and disproportion between ability to hear the voice and ability to hear the watch. The conditions on which presbykusis depended had not been determined, for as yet there had been no opportunities for post-mortem examinations.

Dr. Sexton exhibited a glass ear-syringe and an ear forceps with several attachments.

Dr. E. Dyer, of Newport, R. I., reported on a case of fistula of the helix, in a girl of fourteen, which he had greatly benefited by the application of the galvanic cautery.

The following papers were read by title: "A Case of Chronic Otitis Media Suppurativa, resulting in Cerebellar Abscess, with the Autopsy," by Dr. O. D. Pomeroy, of New York; "Otitis Media Suppurativa, Mastoid Disease, Pyæmia, Mastoid Operation, Recovery," by Dr. G. Bacon, of New York.

Officers for the Ensuing Year were then elected as follows: President, Dr. J. S. Prout; Vice-president, Dr. S. Sexton; Secretary and Treasurer, Dr. J. J. B. Vermyne; Publication Committee, Dr. Vermyne, Dr. Blake, and Dr. J. O. Green; Committee on Membership, Dr. Carmalt, Dr. Kipp, and Dr. Theobald.

Dr. F. L. Capron, of Providence, R. I., was elected to membership.

NEW YORK OBSTETRICAL SOCIETY.

Meeting of February 3, 1885.

The President, Dr. William M. Polk, in the Chair.

Placenta Prævia and Twin Pregnancy.—Dr. H. T. Hanks had recently been requested by Dr. Bull to see a patient with placenta prævia, who, after the seventh month, had lost so much blood that it was decided to effect an early delivery. After giving ether, Dr. Bull introduced his hand into the uterus, seized the foot of the child, and extracted it, not waiting, on account of the amount of blood which had been lost, for uterine contractions. The placenta did not come away at once, and it was found that there was a second child, which also was extracted by the feet. The placenta was double. Very little blood was lost after the extraction of the first child. Both children were living, but one, being quite weakly, died within a few days.

Dr. R. A. Murray inquired whether there had been repeated hæmorrhages, or only a single severe one.

Dr. Hanks replied that there had been slight attacks of hæmorrhage for a few weeks before delivery.

Dr. Murray had made the inquiry because, in his experience, cases of placenta prævia, so far as hæmorrhage was concerned, fell into two classes; those in which there was a slight dribbling of blood for some time before term, and those in which there was but a single attack of hæmorrhage, which was severe and occurred at the onset of labor. In the latter class the hæmorrhage would almost certainly prove fatal to the child. He referred to two instances which could be attested by certain members of the society. In one the woman was in perfect health, and had been out driving the day before an extremely severe hæmorrhage took place, which rendered her pulseless at the wrist and in the femorals, and caused the death of the child.

Sarcoma of the Abdominal Wall and Peritonæum.—Dr. J. B. Hunter related the case of a woman of stout build, forty-five years of age, who, about a year ago, noticed what she called a small lump, just above the umbilicus, which was increasing in size. A month ago the tumor appeared to be about four inches in length and two and a half in breadth, irregular in outline, and situated just above the umbilicus. At the latter point there was an ulceration, which gave forth an offensive discharge. The diagnosis lay between sarcoma and fibroma. An incision having been made across the tumor and the finger introduced, the growth began to shell out like a fibroid from its capsule, but at its lower border, while scarcely any effort was being made, the finger entered the peritoneal cavity, and it was found that the growth was attached to the omentum. It was removed with very little difficulty. The peritonæum was then found to have on its surface little masses of epithelioma which bled easily. Further exploration revealed a second tumor, similar to the one removed, extending from the umbilicus nearly down to the pubes, and apparently covering the greater part of the interior of the abdomen with its flattened surface. It had had no connection with the first tumor. The peritoneal opening made during the removal of the upper growth was two inches and a half in length, and was closed with difficulty on account of the degenerated condition of the membrane. A drainage-tube was inserted into the wound and an iodoform dressing applied. Unexpectedly the patient survived, and had no bad symptoms whatever. The drainage-tube was still *in situ*, and from it some offensive pus had been withdrawn by aspiration. The patient would be able to return to her home, although the malignant disease would remain uncured. Dr. Hunter was disposed to think the growth originated in the abdominal wall.

Ovulation in One Ovary at a Time.—Dr. H. C. Coe referred to an idea which had been termed rather fanciful, viz., that ovulation took place in but one ovary at a time. He had recently observed a few cases which seemed to confirm that view. In three or four instances the patients suffered no pain at one menstrual period, while at the next there was always severe dysmenorrhœa, and in all but one of the patients the ovary on the side to which the pain was referred, the left, was enlarged and prolapsed.

Dr. Hanks asked Dr. Coe if he had observed whether the corpora lutea in the two ovaries were apparently of the same or of different dates.

Dr. Coe replied in the negative.

Dr. Hunter said that in one case of intense dysmenorrhœa, referred to the right ovary, which was enlarged, he removed the ovary and the symptoms disappeared for a year. The left ovary was closely adherent, and was not removed. With the return of the symptoms he attempted to remove the other ovary, but gave up the operation on account of the extent of the adhesions. This case seemed to support the theory mentioned by Dr. Coe.

Dr. Hanks had two patients under observation whose sufferings were much more severe at alternate menstrual periods.

Vaginal Hysterectomy.—Dr. P. F. Mundé presented a uterus and related the following history: About two months ago the woman was sent from the out-door department of Mt. Sinai Hospital to his clinic, and her case was found to be a typical one of epithelioma confined to the lips of a lacerated cervix. Apparently the disease did not extend a line beyond the lips, and, as the case seemed to be a very favorable one for hysterectomy, he advised the patient to have the operation done without delay. But she did not return for two months, and at that time desired to have the operation performed. The lips of the cervix were then much more infiltrated, but the disease had not extended into the parametrium. The uterus was still perfectly movable. The greatest obstacle in the operation was the narrowness of the vagina; it was difficult to expose the cervix in the vaginal vault. The operation was performed on the afternoon of the fourth day before the meeting. As in two former cases he had experienced some difficulty in reaching the broad ligaments and introducing ligatures with the patient upon the side, in the present instance he undertook Martin's method, with the patient upon the back. In this position, however, he found it almost impossible to reach Douglas's pouch, and, on account of the presence of the specula, it was with the greatest difficulty that he was enabled to lift the peritonæum with the finger. In the other cases, with the patient on the side, and using Sims's speculum, this step in the operation was attended by no difficulty whatever. Having finally brought the fundus of the uterus outside the vulva, he was able to pass the ligatures and separate the side attachments with ease. The elastic ligature having broken, he was obliged to use silk upon the left side. Each vessel was ligated separately and little blood was lost—perhaps as much as twelve ounces in all. There was a slight amount of oozing from the posterior incision, between the peritonæum and the vaginal wall, which might have been avoided had he been able to pass sutures as he had tried to do. The operation consumed about an hour and a half. It would have been shortened had the first part been performed with the patient upon the side, turning her upon the back to evert the uterus and ligate the ligaments. The patient remained pulseless at the wrist, and died thirty hours after the operation.

The lessons which the case taught were, first, those concerning the technicalities of the operation, and, second, those relat-

ing to its justifiability. As bearing on the indications of the operation, he referred to a paper which he read at the last meeting of the American Gynæcological Society. The oftener we performed an operation the more dexterous would we become, and the more successful would be the results. In the paper referred to he had maintained that hysterectomy ought to be performed in suitable cases of cancer of the uterus, and he was of the same opinion still, although he might hesitate longer before undertaking it.

Dr. Hanks said he had never removed the uterus, but he had often used the galvanic or Paquelin's cautery in cancerous cases, and he would ask Dr. Mundé whether he would not have been justified in first giving the patient the benefit of a trial of that method of treatment. Was it not just one of those cases in which this form of treatment would have been indicated? If the cautery did not cure the disease, it certainly arrested its progress, and afterward, if necessary, removal of the entire uterus might be resorted to. He had witnessed the hysterectomy in several cases, and he believed that in the majority of instances in this city the result had been unsatisfactory. If, then, we could prolong life six months or a year, or even a longer time, by the old method of partial removal of the uterus, should it not be preferred to entire removal of the organ? He doubted if we were justified in removing the uterus in cases in which the cervix alone was involved; the risk was too great.

Dr. Mundé asked Dr. Hanks in what manner he would operate.

Dr. Hanks replied that he would destroy the diseased tissue by means of the galvanic tip.

Dr. Mundé said he might have done too much, but he thought Dr. Hanks would have done too little. If the patient had declined to have hysterectomy performed, he would then have drawn the cervix down to the vulva, made a circular incision through the vaginal vault all round, and amputated the cervix with the galvanic cautery as high as possible without touching the peritonæum or bladder. He thought this method better than Schröder's, in which the cervix was amputated with the knife and the raw surfaces were united with sutures.

Dr. Hanks had no particular choice as to the manner in which the cervical tissue was removed by the cautery, but the point was that partial removal of the uterus was preferable to hysterectomy. He knew of at least six women who had lived a year, eighteen months, or two years after the use of the cautery.

Dr. Mundé said, in reply to a question, that in thirty-nine per cent. of the cases of removal of the uterus the women had remained well two years after the operation. Seventy-two per cent. recovered from the operation. Those were better figures than could be shown for any palliative treatment.

Dr. Hunter had a patient who had lived nine or ten years after the removal of undoubted epithelioma of the cervix. He thought hysterectomy would ultimately be limited to sarcoma of the fundus.

Dr. Coe had seen Braun undertake to remove the uterus with the patient upon the back, and fail because of the want of room within the vagina.

A Large Hæmatoma.—Dr. Mundé said that two weeks ago a woman came to Mt. Sinai Hospital with the history that six weeks before she had had a miscarriage, and afterward had had fever and a great deal of abdominal pain, and she gave an indistinct history of diffuse cellulitis. By gaslight her complexion was waxy yellow or cachectic. A tumor was found occupying the whole of the posterior portion of the pelvic cavity, the cervix being pushed against the pubic symphysis. It apparently contained fluid, and was supposed to be a pelvic abscess of very large size. The next morning the patient was seen by daylight, and her complexion was less yellow, and this fact, with that of the withdrawal of only blood by aspiration, led to the diagnosis of hæmatoma. The patient's condition was not favorable, but it was believed that absorption of so large a quantity of blood would not take place, and he therefore proceeded at once to make an incision, two inches in length, at the point of greatest tension in the posterior vaginal wall. Eighteen ounces of coagulated blood escaped. A tumor was then recognized within the cavity, of the size, form, and consistence of the human heart. The patient's condition did not seem to justify him in manipulating the tumor to discover its exact nature, but it was thought it might be a sarcoma. The cavity was washed out with a solution of corrosive sublimate, 1 to 5,000, a drainage-tube was introduced, and also iodoform gauze. Within a day or two frequent irrigations with the disinfectant were begun, but the temperature rose to 103° to 104° F., falling after each irrigation. As it was evident that the rise of temperature was of septic origin, the cavity of the hæmatoma was explored, and the tumor referred to, composed of coagulated blood, was found to be breaking down. It was scraped out, and weighed eight ounces; the cavity from which it came measured five inches in diameter. The irrigations had been kept up, the temperature had fallen, and the patient was doing well. He did not think absorption of the fluid would have taken place had it been allowed to remain; the largest hæmatocele which he had known to be absorbed was not larger than his two fists. In this case it was extra-peritoneal.

Perforation of the Cervix Uteri by a Laminaria Tent.—Dr. C. C. Lee related a case which suggested the advisability of caution in using laminaria tents for dilating the cervix uteri. The patient, a middle-aged single woman, entered his service at the Woman's Hospital with what was believed to be a submucous fibroid attached to the anterior wall of the uterus a short distance above the internal os. The vagina was narrow and the cervix long, making it difficult to outline the growth with the finger, and, as frequent hæmorrhages pointed to the necessity of adopting some efficient mode of treatment, it was decided to dilate the cervical canal. Laminaria tents were introduced, carefully watched, and changed sufficiently often. They were held in position by carefully adjusted vaginal tampons, which were never very tightly packed. The uterus was slightly anteverted. On the removal of the tents on the last occasion—they had not been put in by himself, but by a careful and experienced house surgeon—he was astonished to find a large perforation on the anterior surface of the cervix at the internal os. It was evident that these tents, of which two were then in the canal, had, by their expansion and by the pressure of the tampon, perforated the anterior side of the cervix at the vaginal junction. This was the first time he had known the accident to occur, but, on inquiry among his friends, he had learned of two other similar cases, the tents used being of laminaria. In his case, instead of making the usual incision, he divided the cervix posteriorly up to the internal os, and anteriorly up to the perforation, and was then able to reach the greater portion of the tumor. Carbolized cotton was applied to the cervix, and the patient, notwithstanding her reduced condition, recovered. The result of the granulating surfaces was such as to call for trachelorrhaphy, after which the cervix was left in a pretty fair condition.

Dr. Mundé had met with cases in which an ulcer in the wall of a long cervix had been formed by stem pessaries and tents which the physician had failed to introduce through the internal os. In some cases a little force was required to push the instrument through the internal os, and he had no doubt that inexperienced or careless persons might make a mistake and cause an injury of the cervical wall. A laminaria tent would be more likely to cause ulceration than one of tupelo.

Dr. Lee remarked that it was possible the tent used in this case was a tupelo instead of laminaria, but he thought it was the latter. The accident could not have arisen from the cause spoken of by Dr. Mundé, because the internal os was well dilated when the last tent was removed. He could readily understand, however, that, if a tent was not made to pass the internal os, it might press against the solid tissue of the wall and cause ulceration.

Exfoliation of the Mucous Membrane of the Rectum.—Dr. Mundé had recently performed Emmet's operation upon the prolapsed vagina in two cases, the immediate result in both being perfectly satisfactory. In one there was a temperature of from 101° to 102° F., which was not regarded as having any special significance. On the tenth day, when he was about to remove some of the stitches, the house surgeon called his attention to a slough protruding from the rectum. He then examined the patient, and removed fully six inches of the mucous membrane of the rectum, which was gangrenous and very offensive. He supposed there would finally be stricture of the rectum. Was it possible that narrowing of the posterior vaginal wall could have interfered with the rectal circulation and produced the result? In reply to a question, he said rectal etherization had not been employed.

Dr. Hanks referred to a case in which there was discharge of a part of the mucous membrane of the rectum every few weeks, and asked what the treatment should be. This patient had retroversion, and formerly casts of the lining membrane of the uterus were discharged.

Dr. Mundé further remarked that he believed this condition was called exfoliative colitis. About ten years ago Dr. Peaslee presented long casts of the mucous membrane of the bowel. Dr. Mundé had seen two instances, in one of which there was retroversion of the uterus, and in the other chronic oöphoritis. He did not have an opportunity to institute treatment for the rectal trouble.

Dr. C. Mackenzie inquired whether any of the patients had suffered from diarrhœa. He had seen a case in which there was morning diarrhœa, with marked retroversion of the uterus, and more recently a fissure of the anus had been discovered.

Miscellany.

The Failure of the American Medical Association to organize the Ninth International Medical Congress.—The following appeared in the editorial columns of the "Maryland Medical Journal" for July 18th: "Those members of the medical profession who have an earnest and abiding interest in the growth of scientific medicine and in the development of the highest aims of the profession in this country can not but feel the need of a national organization thoroughly capable of meeting the highest purposes of a scientific body. The American Medical Association has undertaken for some years past to represent the real wants of the American profession. It is, however, a delegated body, and in the very nature of its structure contains such inherent weakness that it has not been able to grapple with the serious questions which have been propounded to it. The membership of the association is as fluctuating as its actions, and it has so controlled the interests of the profession as to forfeit the right of respect to which the organization is entitled from the leading minds in the profession. The association has never been able to do the highest order of scientific work, and from year to year has so constructed its offices and committees in the interests of its floating membership that it was not capable of drawing into its ranks the full force and strength of the profession in this country. The association has shown itself totally incapable of dealing with serious and important scientific interests, as has been most conspicuously demonstrated by its recent action at New Orleans in reference to the Ninth International Medical Congress, which it proposed to hold under its auspices. It was shown at New Orleans that a few determined and bold men were capable of capturing its membership and of upturning all of the work delegated to an important committee at its previous meeting in Washington. The result of this action of the association has cast a shame and a blot upon the good name of the entire profession in this country, and it has forfeited all the reputation the association may have had as a fair, liberal, and high-toned scientific body. Under the leadership of a few malcontents the association has degenerated to the level of a ridiculous and pharisaical institution, utterly unworthy of confidence and respect. So far as the fortunes of the International Medical Congress are concerned, it is now evident that the association is wholly incapable of conducting the Congress under its auspices. The withdrawal of the leading members of the profession from all connection with the present organization tells its own story, and very plainly says the Congress must be re-organized on some other basis than the one proposed by the American Medical Association, if it is to be a success. In other words, the association has so seriously blundered in this affair that it must resign its authority as a leading spirit in the re-organization of the Congress. Indeed, it seems to us that the only course now left open to the association is to abstain from further participation in the arrangements for the Congress, and that it leave this matter in the hands of the medical profession at large, which can be depended upon to re-organize the Congress on a successful basis. We have no doubt that the profession at large can move intelligently in this matter. If representative men from all sections of the country can be brought together to confer upon the present outlook of the Congress, arrangements can be made which will bring order out of chaos, and set the affairs of the Congress on a sure and influential footing."

The Missouri State Board of Health announces the appointment of committees to make special investigations as follows:

Prevailing diseases among live stock in Missouri; also condition and care of stock-yards, cars, etc., at points of concentration or distribution—Committee: Mr. Gentry and Mr. Prather. The influential factors in the causation of endemic or local epidemic diseases—Committee: Dr. Griffith and Dr. Homan. The sources, quality, means of distribution, etc., of public water supplies in Missouri—Committee: Dr. Merrell and Dr. Cox. The sanitary care of railway and river transportation lines, including depots, landings, stations, wharf-boats, round-houses, and passenger and sleeping coaches—Committee: Dr. Homan and Mr. Gentry. Domestic and general sanitation in towns, villages, and country-homes—Committee: Dr. Goben and Dr. Griffith. The condition of asylums, poorhouses, jails, workhouses, and other charitable or penal institutions with reference to the health of the inmates—Committee: Mr. Prather and Dr. Merrell. The hygienic care of the school population and of public-school buildings and premises—Committee: Dr. Cox and Dr. Goben.

The Western Society for Psychical Research has been organized in Chicago, the purpose of which is to be commended, since it proposes to investigate certain matters most of which are usually left to enthusiasts and charlatans. From an excellent address by the president, Dr. A. Reeves Jackson, we learn that the work of the society has been divided among five sections: 1. Thought-transference. 2. Hypnotism, clairvoyance, and somnambulism. 3. Apparitions and haunted houses. 4. Physical phenomena. 5. Psychopathy (including what is popularly known as mind-cure, faith-cure, metaphysical treatment, magnetic healing, etc.).

The Nomenclature of Auscultation and Percussion Signs.—The "Glasgow Medical Journal" publishes the following tabular list of terms proposed by the British members and the American member of the committee appointed at the meeting of the International Congress

in 1881 to report on a uniform nomenclature of physical signs which occur in connection with the respiratory system:

PALPATION.

BRITISH LIST. *Dr. Powell and Dr. Mahomed.*	AMERICAN LIST. *Dr. Austin Flint.*
1. Vocal fremitus.	Vocal fremitus.
2. Rhonchal fremitus.	Rhonchal fremitus.
3. Fremitus.	Friction fremitus.

PERCUSSION.

1. Tympanitic resonance.	Tympanitic resonance.
2. Amphoric resonance.	Amphoric resonance.
3. Diminished resonance. Dullness.	Diminished resonance. Dullness.
4. Absence of resonance. Flatness.	Absence of resonance. Flatness.
5. Increased resonance.	Increased or vesiculo-tympanitic resonance.
6. Bell sound. ["This term," says the reporter, "is applied, by some English writers, to a sound produced by percussion, a coin being used as a pleximeter, and the ear applied to the chest. It is supposed to be characteristic of pneumothorax."]	Not included.

AUSCULTATION.

First Group. Varieties of Breath Sounds.

1. Exaggerated. Syn. Puerile. Compensatory. Supplementary.	Exaggerated, etc.
2. Diminished. Syn. Feeble. Weakened vesicular murmur.	Diminished, etc.
3. Suppressed. Syn. Absence of breath sound.	Suppressed, etc.
4. Prolonged expiration. General or local.	Prolonged expiration. High or low in pitch.
5. Interrupted respiration. Syn. Jerking, wavy, cog-wheeled.	Interrupted inspiration, etc.
6. Tubular. Syn. Bronchial. High-pitched blowing.	Tubular. Bronchial.
7. Vesiculo-tubular. Syn. Broncho-vesicular. Harsh, coarse, sub-tubular.	Broncho-vesicular. Syn. Vesiculo-tubular.
8. Amphoric.	Amphoric.
9. Cavernous.	Cavernous.

Second Group. Adventitious Sounds.

1. Rhonchi. Dry musical sounds, (*a*) Sonorous, (*b*) Sibilant.	Rhonchi, or dry bronchial râles. (*a*) Sonorous, (*b*) Sibilant.
2. Stridor.	Stridor.
3. Râles. Syn. Bubbling râles, etc. (*a*) Medium, (*b*) Large. High or low in pitch.	Moist or bubbling râles. (*a*) Medium, (*b*) Large, (*c*) Small. High or low in pitch.
4. Gurgling.	Gurgling.
5. Clicking.	Clicking.
6. Crepitation. Syn. Crepitant râle.	Crepitant râle, or crepitation.
7. Metallic tinkling.	Metallic tinkling.
8. Splash.	Splash.
9. Friction. (*a*) Dry, (*b*) Moist.	Friction.

Third Group. Varieties of Voice Sounds.

1. Increase of vocal resonance.	Increase of vocal resonance.
2. Diminution or absence of vocal resonance.	Diminution or absence of vocal resonance.
3. Bronchophony.	Bronchophony.
4. Pectoriloquy.	Pectoriloquy.
5. Ægophony.	Ægophony.

The Sanitary Convention at Ypsilanti, Michigan, held June 30th and July 1st, was attended by about twenty physicians and health officers from other places, besides the physicians of Ypsilanti, the officers of the State board of health, and a number of prominent citizens. Among the physicians who took part in the proceedings were Dr. Avery, of Greenville; Dr. Vaughan, of Ann Arbor; Dr. Whelan, of Hillsdale, Dr. Kellogg, of Battle Creek; Dr. Palmer, of Ann Arbor; Dr. Kinne, Dr. Wight, and Dr. Lyster, of Detroit; and Dr. French, of Ypsilanti. Much interest was manifested in the proceedings by the citizens of Ypsilanti. These periodical semi-popular conferences seem to be a happy device of the State board of health.

The Editor of the "British Medical Journal," Mr. Ernest Hart, is reported to be a candidate for a seat in Parliament, and to have promised that, in case he is elected, he will vote for the unconditional repeal of the Contagious Diseases Acts (referring to venereal diseases). The "Medical Times and Gazette" remarks that "there is a great excuse for medical men, worried by the everlasting opposition to their benevolent intentions, throwing up the sponge and saying, as Mr. Hart practically does, 'Well, have your own way, but don't blame me if it turns out badly.'"

Boston and the International Medical Congress.—The "Medical News" learns that the following-named gentlemen have asked to have their names added to the list of signers of the resolutions adopted in Boston declining to hold office in the proposed Congress as now organized: O. W. Holmes, William H. Baker, David W. Cheever, James C. White, and William F. Whitney, of Boston; G. P. Conn, of Concord, N. H.; F. H. Gerrish and S. C. Gordon, of Portland, Me.; E. P. Hurd, of Newburyport, Mass.; and Nathan Allen, of Lowell, Mass.

The New York Polyclinic.—We congratulate the faculty of the Polyclinic upon the continued prosperity of the institution. It appears by the annual announcement for the session of 1885 to 1886 that the session which opened September 22, 1884, was attended by two hundred and twenty-nine practitioners. From the beginning the Polyclinic has been under excellent management, and there can be no doubt of its enduring success.

The International Medical Congress.—Dr. W. A. Hardaway, of St. Louis, asks us to state that he has sent in his resignation as president of the Section in Dermatology and Syphilis of the Ninth International Medical Congress. We learn that Dr. Thomas T. Sabine, of New York, and Dr. Thad. A. Reamy, of Cincinnati, have declined to serve in the positions to which they were appointed by the new committee. The "Medical News" announces that Dr. George J. Engelmann, of St. Louis, has resigned from the committee.

The Capias served on Dr. Shoemaker in Chicago has, as we learn from the "Philadelphia Press," been quashed. It was in an action brought against him by a Mr. Merritt, of Troy, N. Y.

THERAPEUTICAL NOTES.

An Untoward Effect of Arsenic on the Skin in Children.—Guaita ("Arch. di Patol. Infantil."; "Dtsch. Med.-Ztg."), who seems to use Fowler's solution freely in the treatment of children's diseases, continuing its administration for four or five months, and increasing the daily amount given from two drops to eighteen or twenty, reports that, in fourteen out of eighty cases, he has observed a peculiar blackish discoloration of the skin as a consequence. It appears either toward the close of the arsenical course or, more rarely, about a month after its completion. It shows itself at first on the neck, and then on the breast, the abdomen, and the hands, while it either spares the face, the lower limbs, and the back altogether or is less pronounced on those parts. It is never accompanied by other disturbances, and it disappears in at least a month, with marked desquamation. It appears from citations in the same journal that a dusky discoloration of the skin was long ago noticed as one of the effects of the prolonged use of arsenic, even in the form of baths of arsenical mineral waters.

Old and New Methods of treating Congenital Syphilis.—Professor Monti, of Vienna, contributes to the "Archiv für Kinderheil-

kunde" an article which the "Deutsche Medizinal-Zeitung" thus summarizes: In the inunction treatment, use has been made of mercurial ointment, oleate of mercury, Beyersdorf and Unna's mercurial-plaster preparation, and mercurial soap. All these substances are very prompt in their action, and, used in proper quantities, never give rise to salivation or signs of irritation of the mucous membrane of the mouth, but they are not suitable for sucklings, for, besides their irritating the skin and producing erythema, eczema, and boils, the too rapid and extensive absorption of the mercury may lead to a quickly developed anæmia, often resulting in cerebral or pulmonary œdema and putting a stop to the child's increase in weight, in spite of judicious feeding. Since the inunction treatment, moreover, neither shortens the duration of the disease nor diminishes the frequency of relapses and sequelæ, the use of calomel associated with iron is much more to be recommended, for instance after this formula:

Calomel	1½ grain;
Lactate of iron	3 grains;
White sugar	45 "

Divide into ten powders.

From one to four are to be given daily, according to the weight of the child.

Calomel may be given continuously, without deranging the digestive apparatus, until all the syphilitic manifestations have disappeared. If, however, in spite of the minuteness of the dose, anæmia shows itself, the treatment must be interrupted at once, and lactate of iron given, or, in case of cerebral anæmia, the ethereal tincture of chloride of iron. After every course of treatment with calomel, Monti uses the following:

Saccharated iodide of iron	15 grains;
White sugar	30 "

Divide into ten powders, from one to three of which are to be given daily, according to the child's age, their use being kept up until there is no longer any enlargement of the spleen and the skin has regained its healthy tint. Monti has observed that, under this method of treatment, relapses are less common and less severe, sequelæ, especially rickets, are lighter, and the children gain in weight.

If intestinal disturbances contra-indicate the internal administration of calomel, or if threatening symptoms seem to call for more energetic treatment, the drug may be used subcutaneously, after this formula:

Calomel	8 to 15 grains;
Gum mixture, Glycerin, each	75 minims.

From half a syringeful to a syringeful to be injected every second or third day, preferably over the chest-wall. Abscesses will often form, in spite of the utmost care in the use of the injections.

Van Swieten's solution (a one-to-one-thousand solution of corrosive sublimate) was used by that author in doses of ten drops, in milk, three times a day, the dose being gradually increased until a hundred drops were taken daily; or he prescribed:

Corrosive sublimate	¼ grain;
Distilled water	10 drachms;
Syrup	2½ "

From two to four teaspoonfuls to be taken daily, after eating.

In the form of baths, corrosive sublimate is very slow in its action, and is employed only when the internal administration of mercury is inadmissible. The following formula is given:

Corrosive sublimate	15 grains;
Chloride of ammonium	2½ drachms;
Distilled water	6 ounces.

To be added to two baths.

Corrosive sublimate is most adapted to injections. [The formula which follows this statement seems to contain a dangerous error; we therefore do not reproduce it.] The injections are generally well borne, although not so well as by adults, and they do their work more speedily than other methods of treatment. Abscesses and indurations of the subcutaneous cellular tissue occur. The duration of the disease and the occurrence of relapses and sequelæ are not affected by the injections; within the first two years of life the treatment should be repeated from four to eight times (being continued from five to twenty days each time), in order to effect a radical cure.

Albuminate of mercury is equally efficient in the form of injections, but the solution does not keep well; it is apt to become turbid, and then it causes abscesses, etc. Peptonate of mercury keeps better, but it has no advantages, and the same is true of formamide of mercury, injections of which are very painful.

Protiodide of mercury is very serviceable, especially in affections of the bones:

Protiodide of mercury	1½ grain;
Lactate of iron	3 grains;
White sugar	45 "

Divide into ten powders; from one to three to be taken daily.

Severe colic and intestinal catarrh are commonly produced by this drug, even when opium is used with it.

Henoch often employs black oxide of mercury, in the form of powders, carrying the dose up to a seventh of a grain, twice a day; but Monti has found that it frequently causes vomiting.

Tannate of mercury, from one seventh to half a grain, from two to four times a day, is very well borne and is quite as rapid and favorable in its action as calomel.

As regards the iodine treatment, Monti gives from three to six pap-spoonfuls [? daily] of a one-per-cent. solution of iodide of potassium, and adds from three to eight drachms of the iodide to the bath. The tardy action of the drug and its interference with the nutrition when its use is long continued have led the author to prefer the saccharated iodide of iron, which is especially well borne by children, never causes iodism, and corrects anæmia; but it is suitable only in cases where energetic treatment is not indicated. For children between three and twelve months old, it is sufficient to give from a third to half a grain, in milk, three or four times a day; children from a year to two years of age may take from four grains and a half to six grains daily.

Silk-worm Gut as a Material for Ligatures.—Guermonprez and Bigo lately submitted a communication to the Paris *Société de thérapeutique* ("Gaz. hebdom. de méd. et de chir.") on the use of *crin de Florence* in surgery. They conclude that, if its ends are cut off and it is macerated for at least a month in a watery antiseptic solution (it must not be boiled), it is the best thread for sutures. It is tenacious, pliable, and better borne by the tissues than either hemp, linen, or silk. For ligatures applied to small vessels it is not so good as catgut, but for large vessels and the pedicles of tumors it is to be preferred.

The Paradoxical Action of Quinine.—Merkel ("Dtsch. Arch. f. klin. Med."; "Ctrlbl. f. klin. Med.") relates the case of a woman who had fever which was taken to be malarial. She was given three grains of hydrochlorate of quinine, and in an hour she showed faintness, weakness, and stupor. She then had a chill, and her rectal temperature rose to 104·6° F. The temperature fell gradually without the occurrence of sweating. The same effects were produced whenever a small dose of quinine was given.

A Dressing for Phagedenic Chancre.—The "Union médicale" attributes the following formula to Terrillon:

Pyrogallic acid	1 part;
Powdered starch	4 parts.

Mix carefully. In cases of ragged phagedenic chancres, with multiple prolongations, the powder is to be blown into the deep parts with a bellows. The application should be repeated twice a day. The preparation should be freshly made and preserved against moisture in a well-corked bottle.

A Diuretic Mixture.—The same journal credits Billroth with the following formula:

Acetate of potassium, Nitrate of potassium, each	5 parts;
Distilled water	200 "
Syrup of raspberry	20 "

A teaspoonful to be given night and morning in cases of acute articular rheumatism. The affected joints are to be painted with tincture of iodine, covered with cotton, and kept absolutely motionless. If pericarditis occurs, a blister is to be applied over the precordial region.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M. D., NEW YORK.

(*Continued from page 87.*)

GALVANIZATION OF THE CERVICAL SYMPATHETIC.—This method has afforded relief, according to published cases, in vaso-motor and trophic disturbances of the nerve-centers, the eye, viscera, muscles, joints, and skin. Thus, for example, cases of cure of epilepsy, atrophy of the optic nerve, Basedow's disease, progressive muscular atrophy, lead-palsy, scleroderma, chronic rheumatic arthritis, bulbar paralysis, neuralgias of various types, and many other conditions have been reported by means of this method. Respecting this step, Erb wisely remarks as follows: "There can probably be no doubt of the correctness of a part of these observations, but this does not by any means imply that the cervical sympathetic is responsible for such results."

When we review the structures which compose the neck and recall the numerous connections which exist between the sympathetic cords, the pneumogastric nerve, the brain and cervical segments of the cord, the medulla oblongata, the brachial and cervical plexuses of nerves, etc., it becomes clear why De Watteville applies the term "sub-aural galvanization" and Erb the term "galvanization of the neck" to this special proecdure.

The steps required to influence these parts by Meyer's method consist in the application of a small electrode (cathode) under the angle of the jaw and adjacent to the hyoid bone, and then crowding it backward and upward against the vertebral column, the positive electrode (of larger size) being placed over the seventh cervical spine. The current may be stabile, labile, or interrupted; or the polarity may be changed from time to time during the sitting of from one to three minutes. Six to ten galvanic cells of the Grenet variety are sufficient. The application may be unilateral or bilateral, according to the demands of the case.

Corning has devised an instrument which insures carotid compression with galvanization of the neck for the treatment of cerebral hyperæmia and some other morbid conditions.

Benedict places the positive pole in the jugular fossa, and the negative pole upon the superior cervical ganglion.

GENERAL FARADIZATION.—This method of administering electricity was first employed by Beard and Rockwell. By this procedure the entire body is subjected to secondary faradaic currents of varying intensity. It is applicable chiefly to those forms of nervous disturbance which are associated with general debility, poverty of the blood, special diatheses and cachexiæ, hysterical affections, skin diseases, persistent chronic inflammations, and other results of low vitality or functional derangements of the organs.

To apply this method, the patient must be undressed or very loosely clothed. The feet are immersed in a bowl of tepid water with a little salt added, in which the cathode is also placed after being connected by means of a rheophore to the binding-post of the secondary coil of a faradaic machine. The anode is held in one hand of the physician, and his other hand (well moistened in salt water) is applied to all parts of the surface of the patient's body. If the subject can bear it, a large electrode covered with absorbent cotton and flannel, or with a soft sponge, is employed in place of the hand. The application should begin at the head and terminate at the feet—the strength of the current being modified from time to time as the feelings of the patient may demand. The extremities and back should have vigorous stimulation, the nerves of the neck should be influenced by a much weaker current, and the cœliac plexus should be influenced by a stabile application of a few minutes over the epigastrium. The entire duration of the application occupies from ten to twenty-five minutes. It may be applied as often as three times a week if necessary.

Personally, I can attest the efficacy of this treatment as a general tonic. I have witnessed immediate effects from it in a large number of my cases, and I employ it constantly in a modified form.

In case the hand of the attendant is to be employed as an electrode, I would advise you to use the instrument which I now show you as a great improvement over the way described by the inventors of this method. It is called the electric bracelet. It is placed upon the right wrist of the attendant over a pad of wet absorbent cotton, and the rheophore is screwed into the binding-post upon it. The right hand is then wet in salt water and used as previously described. By this instrument the hand of the attendant is alone subjected to the current, and the fingers can detect muscular contraction in the patient even when too feeble to be seen easily. As an adjunct to massage, I employ this useful instrument with decided benefit.

GENERAL GALVANIZATION.—The steps required by this method are similar to those previously described, except that the constant-current battery is employed in place of a faradaic machine.

CENTRAL GALVANIZATION.—The cathode is placed over the epigastrium. This electrode should be of large size. The anode is stroked over the forehead, with a current of about two milliampères, for two minutes; then made stabile over the cranium for about two minutes; then moved up and down the neck on each side for the same duration; finally it should be moved along the length of the spine for about five minutes. This method was a favorite one with the late Dr. Beard, who reported cures of gastralgia, hysteria, hypochondriasis, nervous dyspepsia, and many of the symptoms of cerebral and spinal neurasthenia by its continued use. In two cases of gastralgia in which I personally employed it for some time I obtained an absolute recovery.

THE ELECTRICAL BATH.—This method of administration of electricity to a patient may be accomplished by using a metal tub, or one which is composed of a non-conductor. If a metal tub is employed, the patient must be protected

from actual contact with it. This is usually accomplished by means of wooden slats or some other medium of support for the patient when immersed. If the bath-tub is of metal, one rheophore of the battery employed is attached to the tub, while the other is attached to an electrode held by the patient or placed in contact with his body. If the tub is of a non-conducting material, both electrodes may be placed in the water. The electrodes employed should be very large (often running the entire length of the tub), in order to allow of as great a diffusion of the electricity as possible. The fluid in the tub may be simple water, or, preferable, a solution of salt, soda, or an acid.

Personally, I am not a strong advocate of this method of treatment. It violates one of the fundamental principles of electrical treatment of localized affections in that it does not confine the polar action to the part or parts diseased. In the second place, I have not found its tonic action to equal that of general faradization or general galvanization.

Strong claims have been made in its favor as a remedy for tremor (especially of the alcoholic and mercurial varieties) and for chronic articular rheumatism, but I am not yet convinced that they are to be regarded as well-established.

If you desire to try this method of treatment in any case, it is well to know that the temperature of the bath, as well as the strength of the current employed, should be modified by the condition of your patient. The duration of the bath should never exceed thirty minutes, and ten minutes will generally suffice. The current should be strong enough to be perceived by the patient in all cases.

The Relief of Painful Points.—One of the most generally useful effects of electricity is the relief which it affords in many cases to pain. Of all the methods of treatment of neuralgia now employed, I consider electricity, in some of its various forms of application, by far the most efficacious. Personally, I have almost discarded internal medication for the relief of this class of sufferers. You have personally witnessed in one or two cases brought before you the immediate relief which follows the application of electricity to painful points, and you have seen neuralgia cured at one sitting by the same agent. Do not understand me, however, as maintaining that this can be accomplished in all cases. Repeated applications are demanded, as a rule, and, in some instances, months of treatment are required to insure a cure of this distressing malady.

In the majority of subjects afflicted with neuralgia, painful points may be detected along the course of the affected nerve or its branches. These are situated, as a rule, where the nerve gives off a branch or bifureates, and also where it passes through a foramen. Sometimes it is necessary to make pressure along the course of the nerve to detect the existence and seat of these points.

Now, it should be remembered by each of you that the successful treatment of neuralgia depends largely in some cases upon the *direct treatment of these painful points.* They seem in some way to have a relationship with both the production and cure of neuralgia, as well as spasm of the muscles, ataxic symptoms, and other forms of nervous diseases. These points may be the seat of a localized periostitis, a circumscribed inflammatory exudation, a neuritis, an enlarged gland, and many other conditions which create nervous phenomena. In a few instances the symptoms even of ataxia have been relieved, by the electrical treatment of painful points in the region of the spinous and transverse processes of the vertebræ, by men of note, among whom may be mentioned Brenner, Remak, Meyer, Legros, and others.

The steps which you should employ in the treatment of painful points are as follows: 1. Use the galvanic current, employing from three to eight Grenet cells. 2. Apply the anode to the painful spot, and keep it stationary at that point. 3. Place the cathode at some indifferent point, preferably the sternum. 4. Do not use a current which will be excessively painful to the patient, nor exceed five minutes in the application. I frequently do not allow the duration of the current to exceed two minutes at a sitting. It is advisable, in persistent cases, to make the applications daily.

Of late some experiments have been made, with apparent benefit, by having patients of this class wear over the painful points *a piece of metal*, connected with another piece of metal (which is also in contact with the skin) by an insulated wire. The best metals are zinc and copper. They should be brightly polished before the application, and should have a piece of dampened linen between them and the skin. They may be worn continuously for weeks, or changed each day on retiring and rising.

Some authors recommend the employment of *very feeble galvanic currents for an hour or two at each sitting*, the anode being placed over the painful point. Le Fort goes so far as to suggest the propriety of applying such currents continuously for weeks, by means of ordinary rheophores and electrodes, when fatty changes, contractures, or reflex paralyses are to be combated.

OBSERVATIONS ON
PHTHISIS AND PNEUMONIA
IN THEIR RELATION TO SYPHILIS.

A STUDY OF ONE HUNDRED CASES IN WHICH THESE AFFECTIONS WERE ASSOCIATED.

By WILLIAM H. PORTER, M. D.,

PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CURATOR OF THE PRESBYTERIAN HOSPITAL, ETC.

Most of the clinical data used in the preparation of this paper have been taken from the records of one hundred unselected cases recorded at the author's medical clinic at the New York Post-Graduate Medical School and Hospital; the pathological data from the post-mortem records of the Presbyterian Hospital.

Syphilitic pneumonia in children has long been recognized as a distinct and common lesion, but in adults it is

either entirely ignored or given but a passing notice by the writers on clinical medicine.*

Latent syphilis, both of the acquired and congenital variety, as an ætiological factor in disease, has occupied the attention of the author for a number of years past, and he has collected much pathological material bearing not alone upon its influence upon the pulmonary tissue, but upon every organ and tissue of the body. Pulmonary syphilis is best defined as a condition of the lungs in which there is a progressive thickening of the walls of the vesicles; this change is often associated with inflammatory deposits, gummy formations, which, degenerated into cheesy masses, become encapsulated or liquefy, and give rise to cavities. The first is best classified as syphilitic pneumonia, the second as syphilitic phthisis.

The primary origin can only be settled by accepting the terms syphilitic pneumonia and phthisis.

The first necropsy in connection with a typical clinical history was made in 1878, and in this instance there was no question of the existence of acquired syphilis, and the exemption from inherited phthisis was equally positive. The clinical history and the results of the autopsy evidenced a syphilitic instead of a tubercular origin for the pulmonary lesion, and since this time a number of similar instances have been noted.

The lungs removed from a diabetic subject † are interesting, as illustrating several important points:

1. Pulmonary consolidation and softening, with the formation of cavities, may occur in diabetic patients independently of any tubercular phthisical process, which strongly suggests a similar development under other circumstances.

2. Consolidation, softening, and the formation of cavities may occur without the formation of tubercles, as shown by the fact that no tubercle tissue, in the instance quoted, could be made out by the microscope, as well as by the fact of the absence of the *Bacillus tuberculosis*, which corresponds to Koch's theory.

3. Taken together with a number of other necropsies, this one establishes, from a pathological standpoint, the existence of a syphilitic lesion with the formation of cavities at the apex of the lung.

4. It substantiates the clinical observation that syphilitic lesions of the lungs frequently commence and are most marked at the apex, and diminish from apex to base.

5. Both lungs are involved, one usually more than the other. The base and anterior portions of the lungs are rarely involved at first.‡

Every day cases present themselves at the clinic which might be diagnosticated as an ordinary disease and passed by, but a careful investigation invariably reveals a hidden syphilitic taint, which has evidently excited and has served to keep the disease in motion. This assertion may appear dogmatic, but careful investigation leads to but one result. If the rules for diagnosis to be laid down are found sufficiently strong to warrant an inflexible opinion, the main question is settled. From the histories of the first thousand cases treated at my clinic, one hundred, or ten per cent., were taken as the basis of this paper. Of the remaining nine hundred, many had pulmonary lesions and diseases of the various organs, which, in my opinion, were of syphilitic origin, and which, as a rule, responded to a certain line of treatment. This ten per cent. of all the cases is a large proportion; but, if the pulmonary cases alone be taken, fifty per cent. or more would be traceable to the same cause. These facts are sufficient to attract attention, and to indicate how frequently syphilis may figure as a cause of disease.

Of the one hundred patients, fifty-two were males and forty-eight females; but, while these figures are true of this particular one hundred, they do not give the relative frequency among patients at large, for, when the whole number treated was taken into consideration, it was found to be more frequent in females.

The youngest recorded was sixteen years, the oldest sixty-six. The cases taken as a basis for this paper were arranged in ten decades, beginning at ten years, and it was found that six and twenty-two hundredths per cent. occurred in the first, eleven and thirty-three hundredths in the second, twelve and ten hundredths in the third, eleven and twenty-five hundredths in the fourth, seven and seventy-seven hundredths in the fifth, and three and sixty-eight hundredths in the sixth, which shows that its greatest frequency is between the ages of twenty and fifty, with a slight liability of the maximum occurring between thirty and forty.

The question of the disease being an acquired or an inherited vice is one of unquestionable importance. A careful study of this point, for a number of years, has led the writer to believe that pulmonary syphilis in adults is a very common disease, and that it is due to either an acquired or inherited taint, the latter being nearly, if not quite, as frequent as the former. The ground for the belief that the disease is frequently inherited is shown by the number of cases in which it appears in young persons under ten or twenty years of age, whose chastity can not be doubted, and in whom no primary symptoms have ever appeared. In opposition to this view may be urged a primary contagion, passing unnoticed, or a direct transmission by kissing some

Pye-Smith.—Tertiary Syphilis affecting Lung, p. 334.

Mohamed, F. A.—Two Cases of Syphilitic Disease of the Lung (early fibroid). *Op. citat.*, p. 339.

Godhart, J. F.—Syphilitic Disease of the Lung. London, 1874.

Frouenier.—"Gaz. hebd. de méd. et de chir.," 48, 49, 51. Paris, 1875.

Thompson, E. Reginald.—Pulmonary Syphilis. "British Medical Journal," Aug. 28, 1880.

This disease has been recognized and described from Morgagni's time to the present. A much more extended bibliography could be appended, but this is sufficient to show that the lesion has been recognized by eminent pathologists.

older infected person; these are outweighed, however, by the absence of primary and secondary symptoms.

Dr. John Ferguson, of Toronto, reported a number of cases * where the disease occurred in young children, and where, all other treatment having failed, the symptoms yielded to an anti-syphilitic *régime*, and where the father, at a later period, inquired if his children's condition could have been influenced by his having had syphilis.

This is proof positive of the transmission of syphilis during its latent period from a father to his offspring without the mother showing any signs of the disease. The latent period of syphilis, which lasts from ten to twenty years, during which there may or may not be exacerbations, succeeds to the active state, and usually occupies that period of life in which the larger number of children are generated, thus probably accounting for the number of cases where positive symptoms are present without any evidence of primary contagion. A positive proof of the occurrence of this disease in the form of a pneumonia or phthisis may be found in the fact that these complications yield quickly and favorably to anti-syphilitic treatment. The larger percentage among females, especially among the unmarried and virtuous, seems to favor inheritance. These views are those of a clinician and pathologist, and vary considerably from those advanced by syphilologists. The clinical history of a case of this character is explained by the pathological lesion, and *vice versa*. Whether it be of the acquired or inherited variety may be in doubt, but inheritance from the father's side is in keeping with the biblical prophecy of descent even to the third and fourth generations. The recognition of syphilis in causing and maintaining disease, especially when the pulmonary organs are the point of attack, would indicate that a large number were syphilitic and not tubercular in origin.

In many instances patients have come to the clinic with the statement that some competent observer had diagnosticated an incipient phthisis, accompanying it with an unfavorable prognosis. A careful interrogation usually revealed a specific taint, however, and, when the syphilitic pneumonia or phthisis had received anti-syphilitic treatment, they resolved, so that to-day these patients would pass the most critical physical examination. Is there any direct relation between syphilis and tuberculosis? Decidedly not, although clinically and pathologically closely allied, therapeutically they differ decidedly.

The changes found in the lungs are somewhat similar to those of tubercular phthisis, and caused Niemeyer to remark: † "It may be difficult to decide whether the lesion be of a syphilitic origin or not." The lungs may be free, but, as a rule, they are more or less bound to the chest-walls and diaphragm by newly formed connective tissue, so that the pleural space may be completely obliterated. The pleura itself may vary from one eighth to one half of an inch (three and one hundred and twenty-five thousandths millimetres to three and a half millimetres) in thickness. The greatest thickening is at the apices. After bisecting the lung the following changes are found: the main lobes, and often the lobules, are separated by distinct bands of newly formed fibrillated connective tissue, which is not the case in a normal lung. The bronchi, particularly the smaller ones, undergo the same change, while the bronchial glands are indurated and pigmented; the latter, however, is only a coincident lesion. There are numerous cheesy-looking masses which are recognized by a trained eye as gummy formations. Their cut surfaces have a sticky feel and a laminated capsule, which, when they have attained considerable size, is quite distinct. The smaller granules have a similar appearance, and often look as though they could be readily shelled out. These neoplasms may vary, both in size and shape, sometimes occurring as large as a hen's egg, and sometimes so small that they look like the miliary tubercle. They may occur in masses forming cheesy-looking patches, or they may occur in single round and isolated bodies. These masses are separated by degenerated pneumonia or by an interstitial thickening of the pulmonary substance. The early stage is characterized by a diffuse interstitial thickening of the pulmonary tissue, often associated with a degenerative pneumonia peculiar to this disease. In the latter stages cavities are not infrequent, and these are also found in the apex or high in the superior lobe.

The advanced cases are the ones that are usually found on the necropsy table, while the earlier types are not infrequently associated with intercurrent disease or surgical conditions; but here the histories are very incomplete, often being passed without attracting any attention. A striking illustration of this was found in the diabetic case already published, where, in looking for a tubercular process, a typical pulmonary syphilitic lesion was found. These pathological proofs of the apex—rather than the base, and anterior portion of the lung—being the point of invasion are contrary to the ideas of some previous writers, but it has been invariably so in all the cases examined by the writer, both in the post-mortem room and at the clinic. These facts also explain the physical signs which are so marked during life, and substantiate their truthfulness. Macroscopically, this lesion is differentiated from the tubercular by the peculiar cheesy and granular gummy formations which have a tendency to encapsulation, and look as though they could be readily shelled out and easily separated from the surrounding pulmonary tissue.

The microscopic appearances are varied and numerous, and the first thing that attracts the attention is the extensive new formation of connective tissue. In many places broad bands are found closely resembling tendon tissue, and intervening between these tense layers there is a universal thickening of the pulmonary tissue, which also involves the vascular walls. The yellow elastic fibers are larger, and consequently appear more abundant. In many of the cases there is little or no pigmentation found which can be traceable to inorganic substances or to blood. The absence of the first, of course, is indicative of the fact that the interstitial thickening is not due to the irritation of carbon, iron, stone, or any of the other inorganic substances, as in the case of some varieties of fibroid induration. The absence

* Phila. "Med. News," January 17, 1885, p. 66.

† Niemeyer's "Text-book of Practical Medicine," New York, 1881, vol. ii, p. 771.

of blood pigment, on the other hand, is positive proof that it is not due to chronic congestion or impeded blood flow. This also dispenses with the idea that the dyspnœa must be due to the stagnation of the blood.

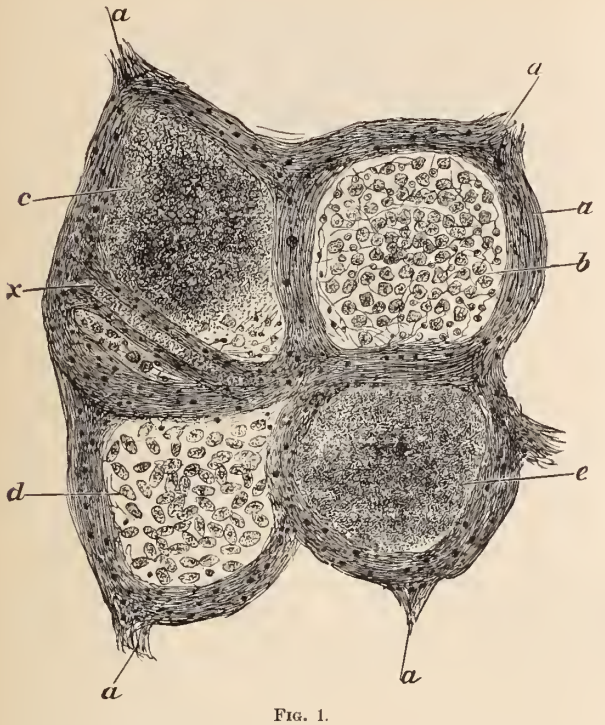

Fig. 1.

The thickness of the vascular walls varies from one twelve hundredth of an inch (20·833 m. m. m.) to one two hundredth (24·999 m. m. m.), but in the majority of the cases they are one eight hundredth to one six hundredth of an inch (31·250 m. m. m. to 41·666 m. m. m). (See Fig. 1, *a*.) In a number of instances the capillaries were seen in the center of these thickened bands (Fig. 1, *x*), the walls of which were thickened independently of the vascular tissue. When the vessels were distended with blood, as in Fig. 1, *x*, the thickness of the tissue intervening between the lumen of the blood capillary and the wall of the air-sac could be measured, and was found to be from one twelve hundredth to one four hundredth of an inch (20·833 to 62·500 m. m. m.).

This would naturally impede the free and easy interchange of gases between the two cavities, and would explain why the dyspnœa in this disease was so profound.

In addition, the connective tissue presents four characteristics microscopically:

1. Dense bands of white fibrous tissue with few corpuscular elements.

2. A less dense tissue studded with numerous small, round inflammatory corpuscles, having an average diameter of one one hundredth of an inch (4·166 m. m. m.). At other points, this same connective tissue was thickly set with oat-shaped corpuscles one thirteen hundredth of an inch (19·230 m. m. m.) long and one eight thousandth of an inch (3·002 m. m. m.) broad.

3. The same inflammatory basement substance, interspersed with round nucleated corpuscles, one forty-five hundredth of an inch (4·166 m. m. m.) in diameter, which, taken alone, looked not unlike a round-cell sarcoma.

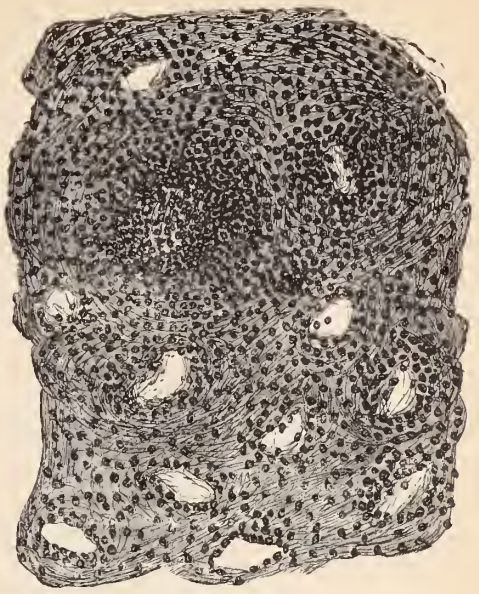

Fig. 2.

4. The thickened bands had a granular and degenerated appearance.

In many of the ultimate bronchi there was marked fibroid thickening, and many of the vesicular spaces were filled with an inflammatory exudation which presented a variety of appearances:

1. The air-spaces were filled with red-blood disks, leucocytes, desquamated epithelium, and fibrillated fibrin identical with that found in the second stage of a lobar pneumonia. (Fig. 1, *b*.)

2. Others were filled with decolorized round cells, as in gray hepatization of lobar pneumonia. (Fig. 1, *c*.)

3. Others were filled with large, round, distinctly nucleated epithelium cells, with a diameter varying from one fifteen hundredth to one two thousandth. (Fig. 1, *d*.)

4. Others contained a granular degenerating material which would not stain. (Fig. 1, *e*.)

The marked feature of this change was that all four conditions were irregularly intermingled as though in each air-sac it ran its course independently of all the rest, going regularly through the red and gray hepatization; at this point degeneration, rather than resolution, set in. The thickened walls prevent absorption, and the degenerating inflammatory products probably account for the copious expectoration.

This process is best classed as a degenerative pneumonia and one peculiar to syphilis. This peculiar pneumonia, associated as it is with diminished elasticity, and with dilatation of the bronchial tubes and loss of resilience on the part of the lungs, explains the absence of both dry and moist râles. The dilated and moist condition of the bronchi accounts for the absence of sibilant or sonorous sounds which are so common in the ordinary forms of interstitial pneumonia. This same condition of affairs accounts for the absence of the crepitant and subcrepitant râles, because the walls of the bronchi are not able to approximate each other and cause the sounds.

My opinion has always been that these râles were due to the opening and shutting of the ultimate bronchi, and a careful study of the physical signs and of a number of sections has still further convinced me that this is the way in which these sounds are produced. But I do not care to say that this is the only way in which they are produced, as they are often heard in certain stages of pleuritic inflammations, and there is no point of diagnosis between the two that is practical. The pleuritic râle, however, is very much less frequent.

It is well known that there is no tidal motion to the air beyond the third division of the bronchi. Beyond this point the air is changed by diffusion and by an anatomico-physiological law.

The trachea and bronchi are lined throughout with columnar ciliated epithelium, and the current of motion produced by these cilia is from within outward at the periphery of the lumen, while the central column of air is constantly moving downward.

It is by this action of the epithelium that the major part, if not the whole, of all inflammatory exudations into the air-sacs and smaller bronchi are brought up to the larger bronchi, where they can be influenced by the tidal air. The mass of sputum is pushed up until it reaches the under surface of the true vocal cords, where it irritates the peripheral sensory filaments of the superior laryngeal nerve, through which it is reflected back to the cough center, when a deep inspiration and a spasmodic or complete closure of the chink of the glottis follow. This is in turn followed by a forced inspiration with the glottis closed, during which the glottis opens, allowing a sudden escape of a large quantity of air under a very high pressure. The result of this is that the mass of sputum is driven through the rima glottidis into the larynx, mouth, or outside world, according to the force of the inspiratory act. This constitutes what is known as coughing, and is simply a dislodgment of the contents of the superior portion of the trachea. Irritation of the peripheral fibers of the pneumogastric in the pleura or bronchi will produce a dry or hacking cough. A thorough appreciation of these anatomico-physiological laws and their application to pathological conditions is absolutely essential for the selection of proper therapeutic agents.

Professor Thomas E. Satterthwaite first called my attention to the true value of the ciliated epithelium. The large gummata have a peculiar laminated, fibro-vascular, connective-tissue periphery which tends to encapsulate and isolate their granular centers. The surrounding pulmonary substance is the seat of a peculiar fibro- and degenerative pneumonia. The capsules are highly vascular, the small vessels having thickened walls from hyaline transformation (Fig. 3, *d*); the center often liquefies, the contents being discharged through a bronchus, leaving a smooth cavity in the pulmonary tissue. These cavities may contract and form a cicatricial "pock-mark," or they may remain stationary for months. On the other hand, they may ulcerate and extend, so that at the necropsy we would find small smooth-walled cavities, together with larger ones with ragged walls, or sometimes with walls similar to those occurring with a tubercular phthisis.

Throughout lungs affected in this way small miliary bodies closely resembling miliary tubercle are abundant, but they are not opaque or transparent. These bodies I have called miliary gummata. These gummata sometimes

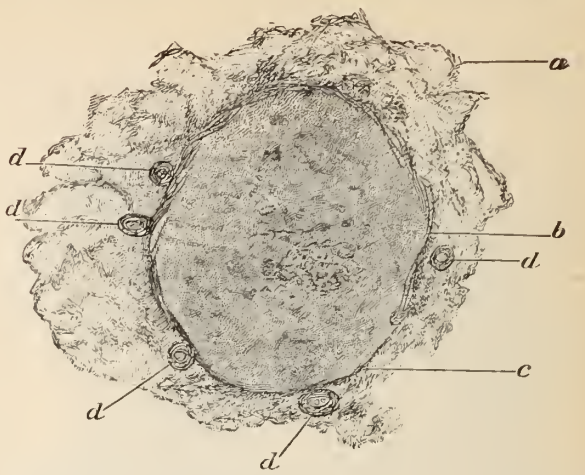

Fig. 3.—Gummy Tubercle showing Cheesy Center, Fibrillated Connective-Tissue Capsule, and Hyaline Thickening of Blood-Vessels. *a*, surrounding pulmonary tissue; *b*, cheesy center; *c*, sharply defined fibrillated connective-tissue capsule; *d*, thickened capillaries showing hyaline metamorphosis.

coalesce, but at first they are round and isolated. A close study of these, in comparison with miliary tubercle, shows that there is a vast difference between the two. The periphery of the gumma somewhat resembles the adenoid tissue of miliary tubercle, but a high power distinctly shows that its periphery is composed of concentrically arranged fibrillated connective tissue in which numerous blood-vessels ramify. (Fig. 3, *b*, *c*.) The walls of these vessels, owing to a hyaline transformation, are invariably thickened. (Fig. 3, *d*.) As a rule, no giant-cells are found in the gumma.

In miliary tubercle the adenoid tissue is more delicate and less perfectly fibrillated; it is full of small-round cells and often contains giant-cells; the capsules are less vascular and the blood-vessels do not present the hyaline transformation.

Taking the definition of Ziegler as the standard for miliary tubercle—i. e., "a non-vascular nodule (*Knötchen*) which does not grow beyond a certain size, and which, having attained a certain stage of development, undergoes cheesy degeneration"—gummy tubercles tend to become encapsulated, miliary to soften and diffuse. Such a striking analogy between these two forms of tubercles naturally suggests the following queries:

1. Is not tuberculosis superinduced by syphilis?

2. In the late stages of a syphilitic lung, may we not also have miliary tuberculosis?

3. Have not gumma tubercles been frequently mistaken for miliary tubercles?

The first two must be answered in the negative on account of the absence of temperature and of the Koch *Bacillus tuberculosis*. There is, however, no good reason why a tuberculosis should not be developed on a syphilitic lesion, but the writer has not found a single instance where the post mortem has revealed this.

Before answering the next question definitely, more data are required to prevent confounding the two.

The rational signs in many respects resemble those of a tubercular phthisis. The patients complain of having had a heavy cold with incomplete recovery, followed by a dry, hacking cough, or one with an abundant muco-purulent expectoration. The sputum is either white and frothy or thick, purulent, and of a greenish or yellow tinge, as in a true pulmonary tuberculosis. Early hæmorrhages are frequent and often copious, while the dyspnœa is an early and pronounced symptom. Pleuritic pains are common, and there is often great weakness while the general physique remains fairly good—in fact, the emaciation is not at all in proportion to the weakness, and is nothing like that of the tubercular variety. The skin is warm and moist, but there is little or no elevation of the bodily temperature. Night-sweats are frequent and distressing, and the patient complains of cephalalgia and of indefinite and wandering pains in the bones and tissues, which increase at night. Dyspepsia and slight jaundice are not infrequent. The urine has a characteristic pale, limpid appearance, which, together with the sallow complexion, often leads to the suspicion of a nephritic lesion. The urinary examination is usually negative unless there happens to be a coincident renal lesion.

Married females abort without any apparent exciting cause further than the syphilitic taint. Their children, if born, are often plump, but soon die of marasmus. The first child is often healthy, but the subsequent children are delicate. Frequently patients complain of sore throat and of an early loss of hair.

The physical signs are peculiar and diagnostic; the respiratory act is labored and all the accessory muscles of respiration are brought into play, but there is little or no expansion of the chest. Early in the disease palpation reveals increased fremitus, but in the advanced cases it is diminished, owing to the small volume of air entering the lung.

Percussion gives varying degrees of dullness, which is most marked at the apex but diminishes toward the base. The percussion-note is dull and of "wooden quality," and localized areas of dullness are found. Owing to the fact that small cavities have thin walls and contain considerable air, the dullness is not so great as would be expected, but, compared with a sound chest, it is decided.

Auscultation yields most positive and peculiar evidence when the rational history is taken into consideration. The inspiratory and expiratory murmurs are prolonged and harsh, especially the former, with a decided intermission between the two. Broncho-vesicular breathing is frequent at the apex. When the amphoric whisper is absent the presence of a cavity is eliminated. As a rule, crepitant and subcrepitant râles are absent, thus eliminating chronic bronchitis. It is differentiated from asthma by the absence of the sibilant and sonorous sounds. The vocal resonance is exaggerated over the consolidated portions. Another very strong and pathognomonic sign is a peculiar pain and œdema of the sternum and of the tibial crests. Pressure over these regions produces a very peculiar pain, which is quite intense and accompanied by a recoil not easily forgotten when once recognized. Patients often try to avoid giving evidence of this, but as surely fail as though trying to resist the muscular reaction to the electric current. A noticeable feature is that when the sternum is excessively sensitive the tibial crests are less so, and *vice versa*. There is no other disease in which this localized tenderness in œdema of the periosteum is met with. It is never found accompanying a true miliary tuberculosis, but it is exceedingly common in connection with syphilis, and, from this absence in cases of tuberculosis where the diagnosis was confirmed by the necropsy and its almost universal presence in cases of syphilis, it may be regarded as pathognomonic of a specific taint. In addition to this, it is always found to yield when the patient is under an anti-syphilitic *régime*.

The diagnosis is based upon five principal signs and symptoms:

1. The abundant expectoration without any signs of softening of the pulmonary tissue.

2. The weak and debilitated condition without marked emaciation and the good rational history of phthisis.

3. Pronounced dyspnœa without any evidence of a cardiac or pulmonary obstruction to the circulation.

4. The peculiar pain and the reaction to pressure upon the sternum and tibial crests.

5. The ready response to treatment is another element in the diagnosis.

The prognosis depends upon the early recognition and treatment. Syphilitic phthisis may run a very rapid course, but, as a rule, it is quite chronic. Dissipation hastens its progress, especially when alcoholic stimulants are used to excess.

In treating this affection, the liver should first be freely acted upon by cathartic doses of calomel or podophyllin, which in some cases should be frequently repeated. Experience has shown that the mixed treatment yielded better results than when mercury or iodide of potassium alone was used. The combination most successful is one sixteenth of a grain of the biniodide of mercury, from five to ten grains of the iodide of ammonium, and ten to twenty grains of the iodide of potassium in a drachm of the compound tincture of gentian, three times a day after meals.

Great reliance is placed on the ammonium salt, not perhaps on account of its intrinsic action in syphilis, but from the action which it has in rendering the two others more soluble, capable of easier absorption and assimilation, and in increasing their solvent action upon these newly formed gummatous elements—in fact, its action may be compared to that of trituration on calomel.

This is, of course, only theoretical, although it was taught by the late Dr. Van Buren, and may not be in keeping with the experience of other observers, but there can be no question of its efficacy in the cases in which it has been tried. Patients have repeatedly come under observation in whom one hundred grains of the saturated solution of the iodide of potassium produced no effect, but who showed rapid improvement after a free catharsis and a maximum dose of thirty grains of the combined salts. It may be argued that recovery under the iodide is no sure proof of the existence of syphilis, as these drugs only prevent a waste of tissue and thus might retard an ordinary phthisis. It is, however, pretty generally acknowledged by writers on therapeutics that the chief potency of the potas-

sium salts and iodine is due to their power of increasing oxidation. Upon this property our theory of their action has been based. Turkish and Russian baths are also of great service. It is quite essential to prescribe expectorants which will render the inflammatory exudation as watery and free from mucus as possible, at the same time stimulating the ciliated epithelium-cells, and thus freeing the air-passages of inflammatory products which tend to decompose, act as irritants, and interfere with the aërating space.

The best of food, air, and a total abstinence from all forms of dissipation must be insisted upon. The inherited cases are the more intractable, and will not yield to the iodide of potassium alone.

The conclusions may be summed up as follows:

1. *Ætiology.*—Pulmonary lesions attributable to syphilis are very common, more so in females than in males, with the maximum number of cases occurring between thirty and forty years of age; it is as frequently, if not more frequently, inherited than acquired.

2. *Pathology.*—Is most frequent at the apex; usually involves both lungs; is a peculiar pneumonic process in the early stages, while later cavities are formed, and it becomes phthisical in the sense of progressive consolidation, followed by softening and the formation of cavities. There is a strong resemblance, but a positive difference, between syphilitic and tubercular phthisis, and a positive anatomical difference between a syphilitic and a miliary tubercle.

3. *Symptoms.*—These are peculiar and diagnostic.

4. *Diagnosis.*—This rests mainly upon the rational history and physical signs, the extreme dyspnœa, the periosteal tenderness, and the absence of an increased bodily temperature.

5. *Prognosis.*—This depends upon an early recognition of the trouble.

6. *Treatment.*—It must be anti-syphilitic to be of any avail. Many cases are unaffected by iodide of potassium alone, unless under enormous doses, but a rapid improvement follows upon the use of the biniodide of mercury, iodide of ammonium, and the iodide of potassium.

In conclusion, thanks must be extended to Dr. George R. Elliot for his pains in examining the specimens for the bacilli, to Dr. George G. Van Schaick for the drawings, and to Dr. E. B. Brunn, one of the laboratory students, for preparing the specimens and examining for the bacilli.

Note.—In addition to the foregoing, I would like to state that, from October 1, 1884, to May 15, 1885, I made forty-two necropsies. In eleven of the cases, or 26·19 per cent., there was, in my opinion, a syphilitic condition of the lung—either gummata or cavities. Each was put to the test for the bacilli of tuberculosis, and in every instance they were found to be absent. The last three of the eleven were also put to the double test for the bacilli of tuberculosis and those of syphilis, and in all of them the latter were found in abundance, but none of the former. One case of the forty-two, or 2·35 per cent., had been diagnosticated as tuberculosis. The sputum was found to contain the bacilli of tuberculosis, and the diagnosis was confirmed by the necropsy.

102 East Thirty-first Street.

"**Bartholow's Materia Medica and Therapeutics**" is, we are informed, to be translated into French by Dr. Henri Huchard and Dr. Lucien Denian, of Paris.

SYPHILIS.*

By F. R. STURGIS, M. D.,

PROFESSOR OF THE DISEASES OF THE GENITO-URINARY ORGANS, AND OF VENEREAL DISEASES, IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO CHARITY HOSPITAL.

The treatment of this affection should be considered both constitutionally and locally. In the old routine of constitutional treatment with mercury for one period, succeeded by another of treatment with the iodide of potassium, the development of the symptoms was so interfered with that the surgeon was left in the dark with regard to the stage and tendencies of the disease. This method fully justified Voltaire's satire: "The practice of medicine was like the pursuit of an imaginary enemy by a blind man armed with a club." Present methods, however, were not open to such a criticism.

Syphilis is a complex disease, which runs a definite course, but which has been subjected to an arbitrary and misleading classification by its division into the primary, secondary, and tertiary stages. It would have been better at the first if it had been divided into the early and the late periods, making the division, not according to the chronological order, but according to pathological phenomena; then the early manifestations would be those where there was no ulceration, while the appearance of an ulcerating process would be indicative of the later period.

The train of symptoms in this disease is usually progressive: first, the chancre and the non-ulcerative lesions of the skin, followed by the destructive processes, with, once in a while, cases where the whole course of the disease is malignant.

In these later cases the chancre becomes phagedenic, and the ulceration, instead of being macular, is pustular and ulcerating, as in the so-called tertiary stage, with which it should be classed. There is no specific treatment for this affection. Although a believer in the use of mercury, I consider its efficacy dependent upon physiological rather than specific reasons; and then we must remember that mercury is not always indicated in syphilis, and is useful in some conditions, but harmful or useless in others. It should not be used in the initial stage. As a rule, the primary sore, *per se*, is of but slight importance, and is serious only on account of its sequelæ. If it is not complicated by improper treatment and dirt, and remains free from phagedenic ulceration and of diphtheritic inflammation, it would get well of itself without recourse to any treatment, and therefore it is best to confine ourselves at this stage to the simplest things possible. Although the books make the diagnosis between the chancroid and the initial lesion an easy matter, in reality it is frequently quite difficult, especially in the mixed sore, where, as is often the case, we have to deal with both the chancre and the chancroid; and, until we are quite sure of the true character of the affection, we should abstain from the administration of mercury, for in the chancroid it causes more or less irritation, and is of no benefit to the patient. Even when the diagnosis of the initial lesion is certain, it is

* Read before the Clinical Society of the New York Post-Graduate Medical School and Hospital, March 7, 1885.

best not to commence the administration of mercury for some little time, as it prevents the subsequent development of the disease, and the maculæ do not appear at the end of the sixth to the eighth week, or at the end of the forty-two days, and the surgeon is consequently left in doubt as to the correctness of his diagnosis. Delay in the administration of the mercury is not detrimental to the patient's future progress, and therefore, unless he be married and rapid healing a necessity, only the simplest treatment for the initial lesion should be employed. Water, lycopodium powder, bismuth, or even a piece of cotton or charpie, to prevent the friction of the mucous surfaces, is all that is required. When further symptoms develop, however, mercury should be resorted to, and its use should be continued through each successive stage. The iodide of potassium is useless at the beginning of the disease, and, in fact, its use only grew up from an effort to compromise between doing nothing and the administration of mercury, which, from its abuse in past years, had fallen into disrepute; but it can only be useful as an adjuvant, and not as a substitute.

That form of mercury should be used which is the simplest and which produces the least disturbance in the system. The chlorides and the iodides are more apt to produce toxic symptoms than other forms. It was observed, during my service in the Charity Hospital, that the patients who were taking the simple blue pill showed a tendency to ptyalism after a meal of salt meat, the salt apparently serving to form the chloride. It is no longer considered necessary to touch the gums, and any symptoms of its toxic effects upon the salivary glands, the gastro-intestinal tract, or other portions of the body, should be avoided, and, before their appearance, the treatment should be suspended or changed.

The simplest form of mercury is the blue mass, two grains of which can be advantageously combined with one grain of iron or quinine, thereby producing a tonic effect. In truth, mercury is itself tonic when administered in small doses, as it increases the number of the red blood-corpuscles; and in syphilis we have to deal with both physical and mental anæmia, the number of the red corpuscles being diminished while the number of the white is increased. Although mercury in small doses increases the richness as well as the number of the red corpuscles, in large doses the effect is quite the opposite. While the administration of the mercury by the simple blue pill is probably the best, we must not discard the iodides and the chlorides entirely, as the former is quite useful in the latter stages of the disease. Where there is a tendency to ulceration of the throat the bichloride is of use, but the gastric and salivary symptoms must be carefully watched during its administration. Calomel is a treacherous preparation, for often, when the patient seems to be doing well under its administration, there is a sudden and unexpected explosion of hydrargyrismus.

The administration of the mercury should be continued until the symptoms have entirely disappeared, when it may be suspended until the development of some fresh complication; hence the treatment of the affection under consideration is largely on the expectant plan. Relapses often occur, but, if treatment is immediately resumed, they become milder and milder until they cease entirely and the patient may be pronounced cured; but whether the disease is entirely eradicated the future only can decide.

This is not very satisfactory, it is true, but, in the present state of our knowledge, nothing more definite can be stated. If, however, I were to be asked whether the condition was curable, I should reply in the affirmative.

The iodide of potassium should be given, owing to its prompt action, whenever there is ulceration about the mouth, nose, throat, or parts of the body where there is danger of any disfigurement; but we should not depend entirely upon this drug to effect the cure, as it is not so positive or so well borne as the mercury. It will often be noticed that, when the iodide has been given to promote cicatrization, while the process will proceed rapidly for a time it will at last be arrested, and the mercury will have to be resorted to to complete the process. Small doses of the iodide are useless, and when it is indicated it should be given promptly and in increasing doses, until the disappearance of the symptoms or the advent of toxic conditions compels its abandonment. It is very readily absorbed and as readily eliminated, and we have no knowledge of its action which can account for its rapid passage through the blood. We do know that while a dose of ten or fifteen grains will do little or no good, one of forty or fifty grains will be followed by an amelioration of the symptoms; yet so rapid is the elimination that it is not likely that more is absorbed in the one case than in the other.

The treatment in skin lesions must be continued until not only the eruption but the staining has entirely disappeared, leaving only the scar, which is indelible, and is one of the few results of this disease that can not be removed.

The initial lesion sometimes leaves a scar, and atrophy, with a depression and whitish scar, often occurs after gummous infiltrations, whether in the bone or elsewhere. Some cases do not tolerate either mercury or the iodide, and this is notably true of those cases which are phagedenic from the beginning. Sometimes it is best, owing to the constitutional debility from excesses of various kinds with which these patients suffer, to institute a tonic and hygienic treatment before having recourse to the mercury or the iodide. The iodide of iron is especially useful in these cases, although the citrate and potassio-tartrate are well borne. Cod-liver oil may also be administered.

Some patients may recover without the use of mercury, but it is not safe to omit its administration, for we can never tell how the disease will end. Mercury, too, is our best remedy for this condition, and it would therefore be indefensible to withhold it and to subject the patient to the consequent risk, especially as the dangers from its effects are less than from the effects of the disease, and the number of recoveries without the mercurial treatment is too small to build a theory upon. Besides being given internally, mercury may be administered by inunction, fumigation, the bath, subcutaneous injection, and by suppositories. The results of the inunction are comparatively favorable, and it has the advantage of leaving the stomach for what it is intended—namely, food and drinks, and not for drugs;

but is uncleanly, and, while it is used quite extensively in foreign countries, Americans will not stand it—they prefer to drench their stomachs rather than soil their skin for five minutes. The old method was to rub in the ointment in different parts of the body consecutively, first the arms, then the legs, and then the back. An objection to this method is that in delicate skins it will produce an eczema, and that it soils the linen beyond redemption, so that in private practice it can scarcely ever be used. A method which is not so objectionable is, after a hot foot-bath, to apply the ointment to the soles of the feet; woolen stockings should then be worn, and then every step will rub the ointment in. There is no discomfort, the feet are not cold, there is no blistering of the skin, and absorption readily occurs. It should be applied every alternate night for a week or ten days; then it should be suspended for a like period. Iodide of potassium should be given when needed, thus constituting the mixed treatment.

The two remedies combined in the same prescription are given by some practitioners, but this is not advisable, as it prevents the increase of one of the ingredients without the increase of the other. It is better to give them separately—the iodide in the saturated solution, which contains about three fourths of a grain, or practically one grain to the minim, largely diluted with an alkaline mineral water, after meals, never on an empty stomach. The proto-iodide or the biniodide may be given in pill form.

A mercurial bath may be given once or twice a week, according to the strength of the patient. Lamps are sold for this purpose. The patient is placed on a cane-bottomed chair, stripped, and covered with a blanket, outside of which is a macintosh. A lamp, having a gutter for water and a cup containing mercury, is placed under the chair. The patient is left in this vapor until after the mercury is completely volatilized and he has had an opportunity to cool off somewhat, when he should be wiped off and put to bed for two or three hours, as in the Turkish bath. The best time for the administration of these baths is at night.

The hypodermic administration of mercury is now about abandoned. When it is employed, a combination of corrosive sublimate or of calomel and albumin is used. It is very inconvenient, however, as it necessitates frequent visits to the physician, and the pain and discomfort to the patient are very considerable. In large bodies of men, as in an army or navy, the first objection would not be applicable, and the method might be found of use.

The treatment by syphilization remains to be considered. This method depends upon the same theory as vaccination, but is subject to the difficulty of the absence of a dilute virus, and that we are not able to predict the future of the syphilized person. The most recent prominent advocates of this theory were Bœck and Ewre, of Christiania. When Dr. Bœck was in this country, Dr. Bumstead allowed him to use the wards of Charity Hospital for the demonstration of the theory, and I had an opportunity of personally observing the method, but I received an unfavorable impression from the start, from the fact that the doctor made no distinction between the chancroid and the syphilitic sore. Both were syphilis to him, while to me they were two very different things, and so I concluded that something was "rotten in the state of Denmark." The method of treatment was extremely disagreeable, and the fact that many of the patients who were subjected to it ran away—which was remarkable, as the class that frequent Charity look upon it as a summer home—attests how much they must have disliked the application. Three sets of inoculations were made each time: first, in the right breast, and from these matter was taken for another set, which were called the daughter sores, and then matter was taken from the last to form the granddaughter set, and then still another group, called the great-granddaughters, beyond which he did not go. There were usually six or seven of these open at a time, and the discomfort was very considerable, so that many said they would rather have the disease than be subjected to the cure, and left the hospital. From this circumstance it may perhaps be said that the trial was not complete, but the non-discrimination between the chancre and the chancroid would have entirely vitiated the result.

As at present all diseases are being caused by bacilli, syphilographers are looking for the discovery of such a cause for this disease. No tissue is exempt from the inroads of the disease. When it attacks the eye, the result may be very serious, and we can not be sure that it will not invade the deep parts and result in blindness. The earlier eye affections are not so serious as the later, for in this disease there is a tendency toward resolution, while in the later affections this tendency does not exist. Atropine is the great remedy in syphilitic iritis, and at one time the ophthalmologists relied upon it alone for the treatment; this is, however, a mistake, for, while the mild case of iritis, like the mild case of syphilis in other tissues, will get well without recourse to mercury, the surgeon should not submit his patient to the risk of treatment without this drug. Where the choroid or the retina is affected, the bichloride is better than calomel or blue pill. The ulcerative throat lesions are coincident with those of the skin, and, where the skin is non-ulcerative, the same is true of the throat. When the throat is affected, the bichloride is the best preparation for use; locally, a solution of the nitrate of silver should be applied for its stimulating and astringent effects. It can not be said to be caustic, even when applied in the solid stick, as its action is so superficial. The sulphate of copper may be used for the same purpose, or the parts may be dusted with calomel. Iodoform is good, but the odor is so intolerable that private patients will not allow it to be used.

The affections of the bones and the nervous system are pathologically the same as the initial lesion, but the one tends to resolution while the others do not. When nodes become soft, resist the temptation to put in the knife, for, while it is good for an abscess to be opened, it is bad for a gumma, as it admits the air to the bone and necrosis ensues, for which operation is hopeless, as no proper sequestrum is formed. In the affections of the nervous system the remedy should be given promptly and with a free hand. The most unpromising cases get well when properly treated, but the iodide must be given in doses which seem appalling when compared with those beyond which we were warned

never to go when we first began to use this drug. One ounce per diem, in divided doses, has to be given frequently. Bumstead reports the case of a patient who took his iodide *ad lib.* He became, in fact, an iodide eater. The rule may be relied upon that no toxic results will occur until the symptoms yield. The remedy should therefore be carried to that point and then dropped. Symptoms that laugh at fifty will yield to one hundred grains, and the necessity for one hundred and fifty or one hundred and eighty grains need cause no alarm. Many physicians will refer to fifteen grains as a large dose, and look incredulous when a dose of fifty or one hundred is mentioned. All practitioners should be prepared for the treatment of syphilis, for it often plays a not unimportant part where not expected, and is an important factor in the diseases of children. In every department of medicine we must be ready to meet it and to expect a cure.

THE USE OF OSMIC ACID IN PERIPHERAL NEURALGIAS.*

By GEORGE W. JACOBY, M. D.,
PHYSICIAN TO THE CLASS OF NERVOUS DISEASES OF THE GERMAN DISPENSARY OF THE CITY OF NEW YORK.

When, in 1883, Neuber (G. Neuber, "Ueber Osmiumsäure-Injectionen bei periphäre Neuralgien," "Mittheilungen aus der chirurgischen Klinik zu Kiel," i) published the results of the treatment of peripheral neuralgias by hypodermic injections of osmic acid, it was to be foreseen that, owing to the good results obtained, other observers would take up the remedy and investigate its action in this regard. Such an inquiry was all the more necessary as the number of Neuber's cases was so small. The cases were old and obstinate ones, and consisted of two cases of sciatica and one of trigeminal neuralgia, which were all cured after ten to twenty-four injections. Only in one case was there a return of the pain, and this was again relieved by the same mode of treatment. The treatment of neuralgias is frequently so unsatisfactory that it is well to have at our command a great many remedies, any of which offer a hope of success. For this reason it becomes our duty to examine into remedies which are supposed to exert an influence upon this affection, whether that remedy *a priori* seems rational or not. Notwithstanding the small number of cases detailed by Neuber, the result attained was so good that Eulenburg ("Die Osmiumsäure-Behandlung bei periphären Neuralgien," "Berliner klinische Wochenschrift," 1884, p. 99) put the remedy to a fair test. He reports and tabulates twelve cases upon which he tried the remedy. The nerves affected were various ones of the upper and lower extremities of the body and of the head. He chose the fresh and not extraordinarily severe cases. The duration of treatment varied from one to six weeks, and the number of injections in the different cases was from three to sixteen.

In a foot-note to his article he says that since then he has treated seventeen more cases, and of these four were cured—two sciaticas, one lumbar, and one intercostal neuralgia. The twelve tabulated cases are as follows:

No.	Sex, age, etc.	Disease.	Total no. of injections.	Result of treatment.
1	35 y., male, machinist.	Right-sided sciatica; fresh case.	8	Cure.
2	43 y., male, merchant.	Right lumbo-sacral neuralgia (affection of n. cutan. femor. ext. and post.), to a slight extent also left-sided.	6	Improvement, but no cure; therefore, galvanic treatment employed.
3	65 y., female.	Left neuralgia brachialis ("neuritis" of single arm nerve-trunks); fresh case.	10	Cure.
4	44 y., female	Right sciatica.	7	Cure.
5	32 y., female.	(Epilepsy) right brachial neuralgia.	4	Only slight improvement; bromides and galvanism.
6	29 y., female.	Left trigeminal and occipital neuralgia.	3	No change; therefore change of treatm'nt
7	49 y., female.	Left trigeminal (Ramus I).	2	No change; therefore change of treatm'nt
8	30 y., female.	Bilateral neuralgia of the (lower) intercostal nerves; fresh case.	5	Improvement slight, result not satisfactory.
9	47 y., female.	Left occipital and cervico-brachial; fresh case.	9	Improvement; later, galvanism.
10	40 y., male, laborer.	Bilateral sciatica; old case, recidiv.	4	No change; change of treatment.
11	53 y., female.	Right lumbo-sacral neuralgia; old case.	10	No change; morphine injections also had no effect.
12	49 y., female.	Multiple (universal) neuralgias, gouty rheumatic basis.	14	No change; other modes of treatment also without effect.

According to this set of cases, then, the result is not very encouraging. In twelve cases there were only three cures, four cases were more or less improved, and five cases were not influenced at all by the treatment. The three cured cases were fresh ones; the unaffected ones were old, complicated or multiple. After this publication I began to make use of this remedy, and should not now publish my observations were it not for reports which have since then appeared, and which certainly show us that we have in osmic acid a valuable remedy for the treatment of certain cases of neuralgia.

Dr. A. Wölfler, in a report from the surgical clinic of Professor Billroth ("Wiener medizinische Wochenschrift," 1884, p. 1495), reports eight cases, which may be tabulated as follows:

No.	Sex, age, etc.	Disease.	Total no. of injections.	Result of treatment.
1	Male, 42 y.	Right sciatica, three years' standing.	16	Cure; no relapse after four months.
2	Male, 50 y.	Sciatica, ten years.	6	Very much improved.
3	Male, 21 y.	Sciatica; fresh case, three weeks.	1	Cure; no relapse after three months.
4	Male, 42 y.	Sciatica, since one month.	5	Cured, with exception of a small painful point in calf of leg.
5	F'male, 56 y.	Left sciatica, one year.	13	Cure.
6	F'male, 62 y.	Trigeminal neuralgia, all three branches.	2	Cure; no attack in four months.
7	Male, 67 y.	Trigeminal neuralgia.	10	Improvem't; relapse after a few months.
8	Female.	Trigeminal neuralgia, Ramus III.		Improved; still under treatment.

This report is so encouraging, and in such contrast to Eulenburg's, that it necessarily requires confirmation by other observers. Of eight cases reported, we have five

* Read before the American Neurological Association, June 17, 1885.

cured, one improved but relapsed, one improved very much, and one improved but still under treatment. In eight cases not a single absolute failure.

James Merces ("Osmic Acid in Sciatica," "Lancet," 1885, p. 58) seems to have had just as much success. He does not give any details of his cases, but says that he has tried osmic acid in eighteen cases "which have resisted all other known methods of treatment." The ages of the patients varied from eighteen to sixty-five. In twelve cases he gave absolute relief for a period of three weeks, the patients then leaving the hospital. In these cases the number of injections varied from one to four. In six he gave temporary relief.

The manner in which I treated my cases was as follows: I made use of a 1-per-cent. solution of osmic acid in water, and of this 0·50 to 1·00, equal to 0·005 or 0·010, of the acid was injected. In a few cases less was used, but very rarely. The preparation was that known as osmium tetroxide, $OS\,O_4$, commonly known in histological research as osmic acid. The preparation known as hyperosmic acid, which was used by Neuber and others, is probably the same. According to the best treatises on chemistry, such a combination does not exist, as no mention is made of it. The solution, when exposed to the light, rapidly becomes decomposed, turning dark and ultimately quite black. Eulenburg says that it can nevertheless be used in this condition, but my experience has convinced me of the contrary. I consider it entirely inactive when in this state. For this reason it should be dispensed only from a dark bottle, and a small quantity only ordered at a time. I have never prescribed more than 20·00 of the solution, this quantity serving for about forty injections. The injections were always made as near as possible to the point of severest pain and into the connective tissue surrounding the affected nerve. The pain caused by the injection is in many cases exceedingly severe, producing a stinging, burning sensation which generally follows the course of the nerve. This pain, however, rarely lasts long, generally subsiding after a few seconds. Occasionally, also, local changes are produced, such as swelling and puffiness over the seat of puncture, and in many cases I have seen a hard, circumscribed thickening of the skin and connective tissue produced in consequence of repeated injections, which only disappeared after days. There is no discoloration produced by the acid except, perhaps, a single black spot where the needle was introduced. The action is a purely local one, no constitutional symptoms whatever being produced. The experiments of Dr. E. Fraenkel ("Ueber parenchymatöse Ueberosmiumsäure-Injectionen," "Berliner klin. Wochenschrift," p. 234, 1884) cast some light upon the action of osmic acid upon living tissues. In three animals he made injections of a 1-per-cent. aqueous solution of the acid, injecting 0·50 to 1·00. The point of injection was, in all three animals, the thigh, as near as possible to the point of exit of the sciatic nerve through the foramen. The number of injections made was, upon the first animal, four; upon the second, six; and upon the third, seven. Upon the second animal after death, which took place twelve days after the last injection, and sixteen days after the first one, the condition found was as follows: Upon removal of the skin, the superficial fascia and the perivascular and intermuscular connective tissue were found to be the seat of diffuse black discoloration. The muscles upon the back of the leg and thigh were atrophied. The sciatic nerve was found to have retained its normal appearance for only half a centimetre below its exit from the pelvis. Below this point it was colored black, imbedded and intimately adherent to the connective tissue.

This condition is found as far as the knee, from where the peroneal nerve may be followed as a clear white cord. Microscopically, the sciatic nerve above the seat of lesion showed normal fibers. A piece of nerve taken from below this point showed nerve-fibers distinctly colored black, their structure being completely retained. The fibers situated more internally, which were not discolored by the acid, were mostly changed, the myelin balled up and granular, and, in another branch, fatty degeneration was noticeable. In those parts of the muscle which were directly affected by the acid an exceedingly severe interstitial myositis was developed. The condition found was, in general terms, a parenchymatous degeneration of many nerve-fibers, and in the muscles a parenchymatous inflammation of the contractile substance, with atrophy. It is very interesting in this experiment to know that osmic acid produces the same discoloration upon the living nerve-fibers as it does upon the dead ones. Whether this discoloration can have any influence upon the action of the nerve can not be answered until our knowledge of the transmission of nerve-force is more positive than it now is.

If various branches of a nerve are affected, it is necessary to inject over each painful branch. These cases will, however, be found to be mostly intractable ones. Certainly the results are better in those cases in which the pain is localized over a single branch. The nerves of the skin do not appear to be at all affected by the injections, and no anæsthetic action was discernible in any of my cases. Of the cases under my treatment, and of which I have made notes, I shall only give three in detail. The first two, corresponding to Nos. 1 and 2 of the table, are taken as examples of the mode of treatment. The third, which is No. 8 in the table, is given for reasons which will become evident when the case is read.

Case I.—A. S., aged twenty-six years. Had been suffering for two years, and had been under my treatment for a right sciatica since February, 1883. The pain started from the upper part of the thigh and radiated downward to the heel. Pain upon pressure over the entire course of the nerve. The pain was so intense when he first came to me that he was unable to sleep at night, and could obtain a little rest only when under the influence of morphine. After six months' galvanic treatment he felt well enough to discontinue treatment, but, after a lapse of two weeks, the pain was as severe as ever, and he again came for relief. This time galvanism, massage, morphine, and the actual cautery were all tried, but in vain. Thus, six more months were passed, until I read Eulenburg's article in the "Berliner klinische Wochenschrift." I then made an injection parenchymatously over the sciatic nerve, between the trochanter and tuber ischii, injecting half a grain of the solution. These injections were repeated three times a week. The first injection was so painful that, notwithstanding all he had already

undergone (actual cautery, etc.), he refused to continue the treatment. The injections were all attended with more or less pain. After the sixth injection the pain had ameliorated to such an extent that he was able to sleep the entire night. Injections kept up. After the sixteenth he was entirely free, and has remained so up to date.

Case II.—T. L., male, aged forty-eight years. Came under treatment in May, 1884. Right sciatica, since six years. Had undergone, besides the usual modes of treatment, also an operation for stretching of the sciatic, but all without relief. Injections were made in the same manner as in the preceding case. The injections always caused considerable pain, but at no time were they unendurable. A translation of parts of a very long letter, written in German and dated April 1, 1885, will give a good idea of the result attained. He begins: "After I had spent months at a time in hospitals during the last six years, and had ultimately sacrificed everything in order to regain my health, a physician in Newark, after a thorough examination of my case, gave me the following advice."

The essence of this advice was that, as a last resort, he should try the osmic-acid injections, for which purpose he was referred to me. He then goes on to say:

"The result of the two to three weekly injections is a remarkable one. I can walk very well, but not for a long period of time. I can sit, lie down, sleep—all without any pain whatsoever; but, on the other hand, I can not stand still. This causes pain. But I believe that this also will change in time."

This patient received in all twenty injections. He had been suffering from a sciatica which disabled him from performing any of the necessary acts of life. He could not sleep, he could not stand, he could not walk or sit. The only position in which he enjoyed comparative ease was stretched out upon his back, and thus he spent the greater part of six years. The result, to say the least, was certainly encouraging.

Case III.—Female, aged forty-five years. Seen in consultation April 12, 1884. Left cervico-brachial neuralgia. Principal seat of pain over the radial in the arm. The pain had existed for two years, and was probably the result of a periarthritis of the shoulder. Every remedy that had been suggested had been tried, but without result. I recommended a trial of osmic-acid injection, and made one myself over the musculospiral nerve. I heard nothing more of the case for a fortnight, the attending physician having promised to continue the suggested plan of treatment. After the lapse of that period of time, on April 26th, the physician called upon me and told me that the case had progressed favorably until three days prior to his visit. The pain had gradually decreased, and prospects of entire recovery were fair.

At the time mentioned he made the sixth injection in the usual place. The patient complained at once of intense pain radiating downward into the thumb and forefinger. The pain at previous injections had been merely nominal. A few hours after that she called again and said that she had a feeling of numbness in the first fingers and along the outer border of the arm. The following morning the physician called upon her and found a well-marked classic, radial paralysis. The patient had during the night slept with her arm thrown backward under her head, and the doctor concluded that he had to deal with a common case of radial paralysis due to pressure.

To me the case was not so clear. The sudden severe pain along the course of the radial after the injection, and the advent of anæsthesia soon after, inclined me to think that the paralysis was due to the injection itself. This view has since then been strengthened in my mind through the publication of Arnozan ("Des névrites consécutives aux injections hypodermiques d'éther," "Gazette hebdomadaire de méd. et de chirurgie," January 9, 1885).

In this article Arnozan calls attention to the occurrence of neuritis following hypodermic injections of ether. He says that in 1881 he accidentally produced paralysis in four cases after injections of ether. In 1883 he saw another case together with M. Salvat, and in 1884 M. Charpentier and M. Barbier published a case of neuritis of the sciatic due to the same cause. In all he publishes seven cases. Of these, six are paralyses of the extensors of one or both hands, due to injections into one or both forearms. The advent of paralysis was immediately consecutive to the injection except in one case, in which the interval between the last ether injection and the occurrence of the paralysis was nine days. Fränkel, in the article already referred to, in the clinical part, says of the experiment upon the second animal: "*After the third injection a complete motor and sensory paralysis of the foot was developed, and upon the third animal a paresis also occurred.*"

In the case of our patient a doubt as to the cause of the paralysis is certainly permissible, especially as the paralysis was not noticeable until the day after the injection, and then may have been due to pressure during sleep. But, in view of these two publications of Arnozan and Fränkel, I feel more inclined to ascribe its production to the osmic acid.

My cases—eighteen in all, including the three already given—have been tabulated as follows:

No.	Sex, age, etc.	Disease.	Total no. of injections.	Result.
1	Male, 26 y.	Right sciatica, old case.	16	Cure.
2	Male, 48 y.	Right sciatica, old case.	20	Cure.
3	Female, 50 y.	Left trigeminal, three years' standing.	3	Improved, but gave up treatment.
4	Female, 35 y.	Left crural neuralgia, fresh case.	5	No change.
5	Female, 30 y.	Right brachial neuralgia, old case.	10	Cure.
6	Male, 37 y.	Bilateral sciatica, old case.	6	No change, examination of urine, sugar, diet and opium, relief.
7	Female, 60 y.	Left trigeminal, old case.	3	Improved.
8	Female, 45 y.	Cervico-brachial, old case.	6	None.
9	Female, 37 y.	Cervico-brachial, old case.	12	Cure.
10	Male, 29 y.	Right sciatica, old case.	18	Cure.
11	Male, 33 y.	Left sciatica, fresh case.	6	No change.
12	Female, 65 y.	Left cervico-occipital; also neuralgia of the III. br. of trigeminal.	5 ove each point.	No change.
13	Female, 40 y.	Occipital neuralgia, radiating pains to the shoulder and arm, old case.	18	Cure.
14	F'male, 45 y.	Right trigeminal, R. I.	4	No change.
15	Male, 30 y.	Right sciatica, fresh case.	6	No change; afterward galvanism; relief.
16	Male, 39 y.	Right sciatica, old case.	17	Cure.
17	Male, 37 y.	Left sciatica, old case.	18	Cure.
18	F'male, 44 y.	Left sciatica, old case.	12	No change.

These cases, then, analyzed, show us, of eighteen cases, eight cures, two improved, and eight unaffected. Of the eight cured cases, five were cases of sciatica. All the cured

cases, including the sciaticas, were old cases. Of the unimproved cases, eight in number, three were fresh cases and two were old. The case marked 8 can not be counted, and of 12 and 14 no note is made.

At any rate, it would seem from these cases that the sciatic nerve is the one which is most impressionable to the action of this remedy, and that old, inveterate cases present a greater chance of success than fresh ones. This is contrary to Eulenburg's experience, and in my cases may be misleading, as I used the remedy only exceptionally upon fresh cases, in the majority of instances using it only as an *ultimum refugium*.

The conclusions justifiable, then, are:

1. We have in osmic acid a remedy which is of service in the treatment of certain cases of peripheral neuralgias, and in some cases where every other remedy has failed.

2. Osmic acid is not an anti-neuralgic, its action is very localized, and it frequently fails where other remedies succeed.

3. Its employment is in most cases very painful and not altogether free from danger.

4. In view of Case 8, it is dangerous to implicate a motor nerve in the injection.

ANTISEPTIC INHALATIONS.

By BEVERLEY ROBINSON, M. D.

(*Concluded from page 65.*)

In my first trials of antiseptic inhalations I made use of Kinnicutt's inhaler, which, I believe, was patterned after that of Roberts. The inhaler I now employ is slightly modified by Ford from Yeo's inhaler, so that the sponge is held by two folds of the perforated zinc-wall, instead of by strings which originally held it in place. I believe the inhaler, as I am now using it, could be perfected in the following ways: 1. The holes in the zinc-plate to be made larger, and thus allow the air to pass through the sponge more freely. 2. The posterior half of the inhaler *not* to be perforated at all, but to consist of one uniform piece on either side. In this way there would be a stronger direct current through the sponge with each inspiratory effort of the person inhaling. 3. A double-valve arrangement, to be placed so as to allow the vapor to pass from the sponge into the respiratory tract during inspiration, and also to permit the expired air to pass directly out from the inhaler without repassing through the sponge. With these modifications properly made, I am satisfied, in certain cases, that the inhaler could be worn almost continuously day and night, and sometimes with great benefit to the patient. The general treatment followed by my phthisical patients was: 1. Malt and cod-liver oil. 2. Compound syrup of the hypophosphites. 3. Iron and arsenic. To the use of one of these mixtures, stimulants, powdered meat, digitalis, and quinine were occasionally added. Counter-irritation by means of iodine, Corson's paint (iodine, croton-oil, and ether), or fly-blisters, was made whenever it seemed indicated. In many cases one of these treatments had already been faithfully carried out before the patients came under my care, and ordinarily, I regret to add, with anything but promising results, in so far, at least, as the rational symptoms of disease were concerned. Of course, with respect to the physical conditions of the lungs previous to the time when I first saw them I could only form a probable judgment, and I inferred simply that as the symptoms of disease had not notably improved, so the alterations of structure had doubtless not retrograded to any marked degree. In more than one of my patients the inhalation used (fir-wood oil, combined or not with chloroform) eased the throat for a long while after using it. In spite of this ease to the throat, the cough was not always arrested; still, the inhalation gave a sort of renewed vigor, and the patient felt decidedly cheered and encouraged. Sometimes the inhalation brings on cough, but not even then does it appear to irritate the throat. Usually the expectoration was rendered much easier; it decreased often in quantity, and, consequently, there was less cough. While using the inhaler one of my patients had a slight hæmorrhage, and was disposed to believe at first that the inhalation occasioned it. Later, and in this same patient, the inhalation (creasote and alcohol) caused no irritation whatever of the throat, and was worn one hour at a time, and about three or four hours in the twenty-four. One patient notably gained several pounds in weight while using the inhaler, and stated that he felt stronger and better in every way than he had previously. When the inhaler was kept on too long, and in those patients who had functional disturbance already of the stomach, nausea was occasioned. No inhaling substance reduced the quantity of sputa to the same extent as turpentine, but this liquid was apt to cause dryness and irritation of the throat, and was frequently replaced on these accounts by creasote and alcohol. Not only were the sputa diminished, as a rule, by inhalation, but several times they showed manifest changes of color. They also became decidedly less thick and viscid, and, from being green-looking and tenacious, they soon were foamy, like soap-suds, and thinner, or showed the aspect of mingled mucus and pus. The breathing was also improved on many occasions, and the patient could make more exertion without becoming flushed and exhausted, or pale and panting. At times the improvement of breathing, of cough, in the amount and character of the sputa, in the appetite, in strength and feeling of more lightness and vigor, was accompanied by physical changes which seemed to indicate improvement in the local condition at the apex, or apices. In one instance, for example, I made a note to the effect (and after three months' use of the inhaler) that the pleuritic râles which had previously existed at one apex during ordinary respiration had completely disappeared, and the breath-sounds had otherwise improved. In other words, they had become more vesicular and less harsh, and the expiratory murmur less prolonged.

Owing to the diminution of cough and the decrease in the abundance of the sputa, the patient's sleep was not so much disturbed—and thus I have found the use of the inhaler during the evening, and even at bed-time, was evidently a greater promoter of rest than cough-mixtures or anodynes. This was true even when direct examination with the mirror had shown that the larynx was red, swollen, and

inflamed, as indeed evidences were already present of incipient laryngeal phthisis. One of these patients stated in emphatic terms that, although she had taken all sorts of drugs for her cough, none of them helped her so much as the inhalation. I would not have my hearers misunderstand me and believe I am of the opinion that in the oro-nasal inhaler we have a panacea for *cough* and other distressing symptoms of phthisis at the first stage. Frequently patients will do well for a time with one kind of inhalation, and we shall feel greatly encouraged; and then, through some exposure or imprudence, or indeed by reason of the steady onward march of the disease, the cough again grows worse and other annoying symptoms return with full force—again and again to be relieved by some new form or combination of inhalation. In one case I employed at different times and during many weeks, extending in all over several months, the following inhalations: At first, inhalations of eucalyptus, then of carbolic acid, iodine and benzoin, later of creasote and alcohol, and finally of fir-wood oil, conium, and benzoin. Each one of these relieved for a time, and afterward lost its beneficial, soothing effect. Still, everything considered, I concluded I had a means which, contrary to Hassall's opinion, was powerful for good, and, despite regrettable failures, was more useful in many instances than steam inhalations or atomized fluids. In not a single instance was I satisfied that the metallic inhaler, when properly employed—and by this I mean when the quantity of fluid poured upon the sponge and the duration and frequency of the inhalation were judiciously regulated—increased the cough except in a very temporary manner, or was productive of any evident bad results. What I have written in regard to the effects of inhalation of vapors of antiseptic fluids in pulmonary phthisis at its first stage is almost, if not equally, true of phthisis at its second stage, and when the pulmonary apices give undisputable signs of softening and breaking down. Even under these circumstances cough becomes less, expectoration is soon more fluid, and, in consequence, more readily raised, and the patients speak of diminished difficulty of breathing and improved rest and sleep at night. In my cases of fibroid phthisis the patients, after a few weeks' use of the inhaler, felt much improved. They could use the inhaler half an hour to an hour at a time, and several times a day, without inconvenience, and stated that they thought the inhalations helped their cough very much. In these cases, also, the sputa diminished notably in quantity and became more frothy, and lost in great part their viscid character. From my limited experience with these cases, I am inclined to believe the fir-wood oil is more useful as an inhalation than any other liquid employed by me.

In laryngeal phthisis the cough in one instance was more frequent and troublesome at first; later it seemed to improve. Certainly the expectoration was looser, although more abundant, and no unpleasant sensations were experienced while inhaling. In one instance the patient increased several pounds in weight while under treatment by means of antiseptic inhalations. No visible changes in the intralaryngeal condition were noted, although repeated examinations were made with the mirror to detect, if possible, such modifications. The inhalation employed in these cases was a combination of one part of fir-wood oil with four parts of tincture of benzoin. A point to which I desire to direct attention in regard to the use of all inhalations is this: Frequently inhalations are useful in allaying cough and the symptoms dependent upon it, even though it is evident that the inhalation does not penetrate below, or even so far as, the larynx. This fact may be explained in two ways: First, as is well known, the cough may in reality be occasioned by a morbid condition in some part of the respiratory tract, preceding the lungs in location, and although the lungs or bronchial tubes may also be inflamed. This morbid condition may be an elongated uvula, post-nasal catarrh, follicular disease of the pharynx, acute or subacute laryngitis, etc. Again, in the use of all forms of inhalation, while the soothing and modifying effects of it are partly due to their direct local application, still there are similar effects produced by their absorption by and elimination through the mucous membrane lining the parts referred to. A final question in regard to phthisis and antiseptic inhalations should here be mentioned. Do they destroy the *Bacillus tuberculosis*, or do they affect notably its growth or vitality? *Personally*, I have never searched for tubercle bacilli after the oro-nasal inhaler had been worn a considerable time, and in which, previous to wearing it, these characteristic micro-organisms had been found. In one case, however, a careful microscopic examination of sputa was made by my house physician when the patient was known to have evident pulmonary phthisis as shown by indisputable physical signs. At the time the bacilli were first discovered, inhalation of antiseptic vapors had not been employed. Several months later, and when during the intervening period a metallic inhaler had been worn during several hours each day, a second microscopic examination of the sputa was made and still showed a large number of bacilli. The precise relative number of these organisms observed on each occasion is not mentioned in the history of the patient, nor is it stated whether there was any proof to show that the bacilli had less vigor than when first detected. What is known definitely is this, viz.: that, although bacilli were present in considerable numbers at the time of the second microscopic examination, the patient herself, both as regards her physical condition and her rational symptoms, had evidently much improved. How much the improvement was directly due to the use of continuous inhalations it was impossible to affirm positively. There was no doubt, however, as to the fact that they had been useful and comforting in allaying cough, diminishing faucial irritability, and promoting the ease of expectoration.

If other observers be consulted, I am not aware that, up to the time of writing, anything more definite can be obtained in regard to the mortuary effects of inhalation on tubercle bacilli than what I have stated.

Whether or not, therefore, dry-vapor inhalations in c on centrated form are able to destroy tubercle bacilli is not yet satisfactorily determined. That they are powerful to arrest or prevent fermentative and putrefactive changes of the sputa; that they can modify the terminal bronchi and lung-cells so that they will secrete less purulent matter for expectoration—so much at least results from direct clinical observation and

experience. It is also highly probable that continuous dry antiseptic inhalations are able to weaken and partly devitalize the infective germs upon which the origin and growth of pulmonary phthisis largely depend, according to the present state of our knowledge. The manner in which this is accomplished is apparently either by direct action upon these organisms or indirectly by rendering their surroundings and the location where they are deposited very unfavorable to their extension or propagation. It is perhaps true, and it is certainly conceivable—by reason of analogy with other means by which some organic germs are killed—that such an effect may be produced by prolonged or frequent inhalations of antiseptic volatile agents of moderate concentration, as well as by shorter inhalations of very strong vapors. This is a most fortunate circumstance, since it is proved that the continuous inhalation of concentrated vapors of antiseptic substances, in any notable quantity, is rendered impossible by the intolerance of the respiratory mucous membrane to their contact.

The power such inhalations may have will depend, in my opinion, upon several distinct factors: 1. Upon the form and efficacy of the inhaler itself. 2. Upon the substance which is used and its strength. 3. Upon the frequency and less or greater continuance of the inhalations. 4. Upon the stage which the pulmonary phthisis has reached, upon hereditary influences, hygienic surroundings, and individual vigor of constitution.

Having already taken up much of your time and attention, I shall be brief in my remarks about my other cases. In fact, I do not consider those in regard to which I have preserved notes as sufficiently numerous to warrant any strong affirmations. Still, as my memory serves me about several cases of each disease treated by inhalation, in some particulars at least, I trust that what I may say has more value than would be apparent but for this prefatory statement.

A. In *laryngitis*, acute and subacute, antiseptic inhalations are decidedly useful. They quiet irritation, lessen hoarseness, diminish cough, change the aspect of the inflamed mucous membrane, and, in certain cases at least, evidently hasten the disappearance of symptoms and the establishment of a cure. In one case, in which there were concomitant post-nasal catarrh, pharyngitis sicca, and paresis of the tensors of the vocal cords, producing hoarseness, there were also "a red, swollen epiglottis, arytenoid cartilages, and ventricular bands." In this case there was moderate cough. Still it persisted and caused much mental distress, despite various medications internally, and numerous local applications of pigments, sprays, and powders. One week after inhalation was begun the cough had disappeared completely. The larynx was less inflamed, the pharynx was not at all glazed, there were little or no frothy sputa, and, indeed, the patient was so far recovered that the remedy was stopped. This had consisted of ten drops of turpentine, used in Kinnicutt's inhaler, during five minutes every three hours.

B. In cases of *chronic nasal catarrh* the following effects were noted: A singer, having post-nasal catarrh, hypertrophy of the turbinated bodies, slight pharyngitis sicca, and catarrhal laryngitis, secondary to the other affections. This patient made use of inhalations of pine-needle oil, and soon remarked that these inhalations rendered the discharges from her nose, especially anteriorly, very much less. The breathing also became notably freer. In fact, after two months' use of the inhaler, she had very slight trouble, if any, with her anterior nasal cavities. There still remained, however, some discharge from the naso-pharyngeal cavity. It is only fair to state that in this case, as well as in my other cases of catarrh of the nose, I made use, concomitantly, of other local treatment as an adjunct. Still, by comparison between the cases of nasal catarrh in which dry-vapor inhalations were employed and those in which these inhalations were not used, although other remedies were made use of, I believe that the inhalations were undoubtedly beneficial in the manner stated above. In three cases, in which marked dysphonia was obviously caused by the catarrhal inflammation of the nose, inhalations of benzoin and of benzoin and fir-wood oil produced marked benefit to the voice and general condition of the throat and nose. In one case, where the nasal duct had become obstructed by reason of pituitary hypertrophy, and there was consequent epiphora, this symptom, among others, was apparently relieved *in a measure* by inhalations, and the swollen membrane was reduced in thickness.

C. *In subacute and chronic bronchitis*, inhalations of tincture of benzoin and fir-wood oil—one part of the latter to eight parts of the former—after one or several weeks, diminished the cough, expectoration, and hoarseness. In one instance the patient stated distinctly that the cough was stopped by the inhalation. The amount of fluid used was 10 to 15 drops, one or more times during the day, and the inhalation was repeated ten minutes every three hours.

In a case of chronic dry pleuritis the first few inhalations produced cough, with expectoration. After a time the patient felt convinced that the inhalation was of benefit to him. "He coughs less now than formerly, and there is much less expectoration."

In one case of chronic laryngitis there was decided improvement after only a few days' treatment.

In my case of paralysis of the tensors of the vocal cords, and in one also of chronic pharyngitis, decided amelioration was shown after a time, owing to the use of the perforated metallic inhaler.

DISCUSSION.

Dr. F. C. Shattuck, of Boston, said the paper confirmed him in certain views concerning antiseptic inhalations which were partly preconceived and partly based upon experience. Some years ago, when antiseptics first began to be used by inhalation, he administered them to certain patients. He found carbolic acid to be very disagreeable; it was difficult to induce patients to wear the inhaler containing it. He could not say whether or not they were of any benefit, but perhaps he employed the inhalations too strong, and possibly under other circumstances the results would have been better. Certainly it was very desirable to get something which would simply allay cough. If by means of such simple remedies as these inhalations we could diminish cough and irritation, we should certainly do our patients a great service, and the service was no less if it enabled

us to dispense, even only to a degree, with the use of opium. Dr. Hassall's book upon the subject of inhalations was a very interesting one, but his statement of the case seemed pretty strong. If one put a few drops of an antiseptic, say of carbolic acid, thymol, creasote, etc., on a sponge, and found at the end of two hours' inhalation that three quarters of the remedy could still be detected in the sponge, certainly the amount of the drug which could have effected an entrance into the lung must be very small. That, it would appear, was reasonable ground on which to distrust this method of treatment. Acting upon these observations, Dr. Hassall had constructed his inhalation chamber, and it would be interesting to see what would be the practical working of it.

Dr. Boardman Reed, of Atlantic City, inquired of Dr. Robinson whether he had used ether or cocaine by this method of inhalation. It had occurred to him that, inasmuch as these agents had been found so valuable in other directions, they might also prove valuable when inhaled in allaying cough, particularly laryngeal cough.

Dr. P. Kretzschmar, of Brooklyn, thought the tables referred to only went to show that there had been a change in the condition of the sputa after the use of the inhaler.

Dr. B. F. Westbrook, of Brooklyn, thought the benefit which Dr. Robinson had produced with this mode of treatment could be referred to two factors: First, the favorable influence upon the mucous membrane of the upper respiratory tract of an atmosphere kept constantly at the same temperature. This every one knew to be a very important matter in irritations of the respiratory apparatus. It was known that cough, especially when violent, almost always had its origin in the trachea or above it, although possibly in the bronchi, and a continuous supply of uniformly warm, moist air undoubtedly had a very soothing effect upon this part of the respiratory tract. Besides, balsamic vapors, which Dr. Robinson had employed, when inhaled even in very small quantities and for some time, had a very markedly soothing and beneficial effect upon the irritated membrane. It seemed to him that the allaying of the nasal and post-pharyngeal catarrh, the laryngitis, and the bronchitis, would account for all the good results which Dr. Robinson had observed. Anything which would give the consumptive rest would increase his appetite, improve sleep, and prove of benefit to his general bodily condition. Furthermore, Dr. Robinson had given his patients cod-liver oil, malt, and such agents as would improve general nutrition. Dr. Westbrook did not think that irritation at the apex of the lung would be more likely to produce cough than irritation of any other portion of the lung. At least he knew of no proof of it. Dr. Robinson had mentioned congestion and œdema of the base of the lung as not being accompanied by cough, but it was also very well known that pneumonia of the apex was not accompanied by cough, while the withdrawal of a sufficient amount of pleuritic effusion to exert considerable influence upon the lung usually led to violent coughing. He therefore thought it hardly warrantable to say that irritation at the apex was peculiarly liable to produce cough.

The President (Dr. A. L. Loomis) remarked that the element of cough in phthisis was a very large one, particularly in the third stage, violent paroxysms occurring as the result of pleuritic adhesions. One often saw cases in which the only evidence of phthisis was the presence of fine crepitation at the apex or some other portion of the lung, and yet the patient was a sufferer from the most violent paroxysms of coughing, without there being apparent physical signs in the bronchial tubes or upper air-passages. His experience with inhalations had led him to believe that they were of use only so far as they acted as anodynes to the upper air-passages. He, perhaps, was prejudiced against their use, for his experience with them had been somewhat unfortunate. Their use had in a few instances been followed by profuse hæmorrhage. He would not say that the inhalations caused the hæmorrhages; he would only say that two or three cases, occurring at short intervals, had led him to be careful.

Dr. Robinson, in closing the discussion, said, in reply to Dr. Reed's question, that on one or more occasions he had used a small quantity of ether as an inhalation, either alone or combined with balsamic vapors, and he thought it produced some irritation, although it was very volatile. Certainly ether very generally produced more or less irritation, and it was but natural that it should do so in these conditions. He therefore preferred chloroform to ether. As to cocaine, he had not supposed that it would be of any benefit inhaled, and had not employed it. He had, of course, used it as a spray or with the brush in troubles of the respiratory tract. As to the susceptibility of the upper portion of the lung to irritation and the production of cough, of course he could not prove the point positively. He had concluded, from examination of the sputa in these cases, that they had come at least as far as from the lung structure, and, with the physical conditions present, it seemed fair to suppose that they came from the air-cells. It had been stated in the discussion that benefit from the inhalations was due to allaying irritation in the nasal cavities, larynx, pharynx, and trachea. He too thought that we should seek to know the real source of benefit derived from our treatment. He had only stated that in the use of inhalations we should, as far as possible and without causing undue irritation of the respiratory tract, make the air inhaled as pure as we could. That was what he had endeavored to do, and he had employed small quantities of the drug because large amounts caused irritation. If wealthy persons went to pine regions and to the Adirondacks in search of pure air, with the expectation of being benefited thereby, it was but natural to suppose that the poor of New York city would be benefited by placing themselves in a condition approximating as nearly as possible the surroundings of such regions. While he agreed with the president that in a great many cases pleuritic adhesions might be the cause of cough in phthisis, yet his observation had not led him to believe that they occurred as frequently as many authorities had stated. He thought the irritation often centered in the lung itself, and was frequently allayed by favorable atmospheric conditions reaching the lungs themselves.

Edited by Frank P. Foster, M. D.
NEW YORK, SATURDAY, AUGUST 1, 1885.

THE INTERNATIONAL MEDICAL CONGRESS.

With admirable self-control, the profession refrained until after the new committee had done its work from giving vent to the widespread indignation that the action of the American Medical Association at New Orleans gave rise to. In the same issue in which we gave the proceedings of the New Orleans meeting we sharply rebuked its course in the matter of the Congress, and shortly afterward the "Journal of the American Medical Association" characterized it as "of questionable propriety." We insisted at the time that the movement for a reorganization had its rise in the bitterness of personal disappointments, and not in any genuine feeling that the original committee had acted otherwise than in the true interest of the Congress. But, as we have said, the profession at large reserved its judgment until after the work of the new committee had been made known, although it had all along been difficult to see how that committee, practically only a ministerial body, could accomplish anything in palliation of the destructive course that had been entered upon at New Orleans. Any lurking hope of this sort that there may have been was seen to be groundless when the results of the Chicago meeting were learned, and the profession in most of the great cities were prompt to express their condemnation. So rapidly did the new nominees in one city after another—Philadelphia, Boston, Baltimore, Washington, and Cincinnati—declare that they would take no official part in the Congress under the new organization that it became evident that the undertaking was doomed to ignominious failure unless a complete reversal of the New Orleans action could be secured. We have for some time been convinced that nothing short of that would satisfy the profession and restore any reasonable hope for the success of the Congress. We have felt, too, that this end was most likely to be accomplished by getting as full and prompt an expression as possible of the feelings of the profession. Of late it has looked as if these withdrawals, which at first threatened to confirm the wreck of the Congress, would really lead to the radical remedy we have mentioned, and also to the far more important result of lifting the American Medical Association out of the low position it has brought itself to occupy.

The new organization still has its defenders, however. They are no longer confident, and they have been put on the defensive; but it is evident that they will not give up their undertaking until they are compelled to do so. The tenacity of their purpose is shown by their latest tactics. Realizing the effect that is sure to be produced by a continuance of such action as that taken in Philadelphia and the other cities that we have mentioned, and the informal action taken by individuals elsewhere, they are now trying to persuade those who have not yet declined not to do so. They hold out the consideration that it is unnecessary and quite out of character for a man to decline a position until he has been officially notified of his appointment. As the secretary can take his own time about notifying the appointees, it is evident that, in case he avoided sending out notices, and the appointees could be made to take the advice mentioned, they would have the game in their own hands. It is nearly a month since the appointments were made public, and it seems to us that any of the appointees who hesitate to declare their intentions, simply because they have not been officially notified, can only be compared to the man who, seeing a man drowning, refrained from interfering, on the ground that he had never been introduced to him.

Another device to which they are resorting is that of affecting to look upon the dissatisfaction that has been expressed as not really due to their revolutionary scheme of reorganization, but simply to the unpopularity of the secretary, Dr. Shoemaker, and it is hinted that that gentleman will be induced to resign, with the result of calling back those who have declined, and restoring harmony. It is needless to say that nothing could be more absurd than the pretense that Dr. Shoemaker's unpopularity, in case it exists, is at the bottom of the serious action that has been taken. It is little short of ridiculous to bring forward so paltry a matter as being the cause of so important a step. But, even if there were any truth in it, Dr. Shoemaker is not the man to allow himself to be cast overboard as a Jonah. We must conclude, therefore, that the petty nature of all that can be said in favor of the reorganization augurs well for the hopes of those who recognize that nothing but its overthrow can save the Congress.

DEMAND AND SUPPLY AS APPLIED TO PHYSICIANS.

The constant tendency of our teaching bodies, quite independently of the urging that has come from the profession at large, and the striving of the latter, wholly apart from any demand on the part of the community, toward improvement in medical instruction are as gratifying as they are evident. We believe that within certain limits the matter may safely be left to these agencies. Therefore we have never looked upon proposed legislative enactments bearing upon it as quite the panaceas that their authors have seemed to believe them. We have insisted that a uniform standard of the qualification to practice, whether high or low, was impracticable under existing circumstances. If too high, it would reduce the number of practitioners below the force needed in a sparsely settled country; if too low, it would not meet the fair demands of the older sections.

That the first of these contingencies is not altogether imaginary is beginning to be found out even in so compact a community as that of England. The "Medical Times and Gazette," of London, lately said: "Assuming for a moment, what might perhaps claim to be more than a mere assumption, that the well-meant strictness of the Medical Council is really cutting off

the supply of qualified practitioners in poor and distant neighborhoods, and throwing their inhabitants into the hands of quacks and herbalists, who is there to warn the Council of this result?" It is doubtless a source of annoyance to a man who has spent all the time and money that could be spent to advantage in attaining to a thorough mastery of the medicine of the present day to be classed by the community only as one among little short of a hundred thousand possessors of the degree of M. D., and it is no less an annoying and humiliating circumstance that foreign critics almost invariably hold up our weaker educational institutions as specimens of what we are able to produce. All this is inseparable from the young and undeveloped state of the country, and it should be endured with resignation, as a sort of sacrifice to "the greatest good of the greatest number."

It has often been said to our discredit, and often complained of by the unsuccessful among us, that the proportion of the medical body to the population was far in excess of what was to be found in other countries. We have before expressed the conviction that this excess had not the same significance that it would have in a densely peopled country, and we believe that the great numbers of "young doctors turned out" every year, as the phrase runs, are not an unmitigated evil.

MINOR PARAGRAPHS.

AN INJUSTICE TO A DISTINGUISHED PHYSICIAN.

The "Medical Times and Gazette" gives a summary of a statement by Professor Warlomont, of Brussels, a distinguished ophthalmologist, and a man well known for the energy and ingenuity he has displayed in the study of animal vaccination, as well as for his admirable report on the famous Louise Lateau case. The story was published in the "Presse médicale belge," and it sets forth the circumstances of an injustice to which Dr. Warlomont has been subjected. He has been dismissed arbitrarily from the post of director of the Ophthalmological Institute, the only reason given being the fact that the state of his health had made it necessary for him to go abroad for a few months during the past year, for which he had obtained the permission of the authorities. During the thirty years of his service he had never before been a week at a time away from his post. The managers superseded him by abolishing his office. The pension to which he was entitled was refused him on the ground that it could only be gained by a person who had attained the age of sixty-five years. He lacks less than a year of having arrived at that age, and it looks as if his dismissal had been abruptly and hastily brought about, as our contemporary intimates, with the intention of depriving him of this acknowledgment of his services.

NEWS ITEMS, ETC.

The Plymouth Epidemic.—The memorable epidemic of typhoid fever at Plymouth, Pa., is now announced to have so far subsided as to be practically at an end. The relief committee has discontinued its work, and the hospital was to have been closed yesterday.

Chicken-pox mistaken for Small-pox.—That unsavory suburb commonly known as Hunter's Point, but which rejoices in the high-sounding corporate name of Long Island City, seems likely to have a suit for damages to defend, according to the newspapers, as it is alleged that the authorities ordered the removal of a man who seemed to have small-pox to the hospital on North Brother Island, where it was discovered that he was only suffering from chicken-pox. He was kept in the hospital eleven days.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 28, 1885:

DISEASES.	Week ending July 21.		Week ending July 28.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	0	1
Typhoid fever	10	2	16	6
Scarlet fever	40	14	29	6
Cerebro-spinal meningitis	4	3	2	1
Measles	48	8	34	8
Diphtheria	59	23	34	21
Small-pox	2	0	1	1

The Health of Connecticut.—We learn from the June report of the secretary of the State Board of Health, Dr. C. A. Lindsley, that the death-rate of ten cities in the State was 16·6 in 1,000, against 18·6 for the month of May. Hartford and Norwich, however, showed 23·4 and 20·4 respectively. Dr. R. M. Griswold, of North Manchester, reports an endemic of quinsy, laryngitis, and bronchitis as manifestations of malarial poisoning.

Sir Guyer Hunter is reported, says the "Medical Times and Gazette," to have been selected as a candidate for a seat in Parliament.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 19, 1885, to July 25, 1885:*

Elbrey, F. W., Captain and Assistant Surgeon. Sick leave of absence further extended four months on surgeon's certificate of disability. S. O. 162, A. G. O., July 17, 1885.

Strong, Norton, Captain and Assistant Surgeon. Ordered for temporary field duty with battalion of 8th Cavalry at Hillsboro, N. M. S. O. 34, Headquarters District of New Mexico, June 27, 1885.

Everts, Edward, First Lieutenant and Assistant Surgeon. Ordered for duty as post surgeon, Benicia Barracks, Cal. Par. 3, S. O. 70, Department of California, July 15, 1885. (Modifies Par. 2, S. O. 68, C. S., Department of California.)

Winne, C. K., Captain and Assistant Surgeon. Ordered for duty at Benicia Arsenal, Cal. Par. 3, S. O. 70, Department of California, July 15, 1885. (Modifies Par. 2, S. O. 68, C. S., Department of California.)

Society Meetings for the Coming Week:

Monday, *August 3d:* Utica, N. Y., Medical Library Association; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Chicago Medical Society.

Tuesday, *August 4th:* Elmira, N. Y., Academy of Medicine; Buffalo, N. Y., Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Hudson County, N. J., Medical Society; Hampden District, Mass., Medical Society (Springfield); Androscoggin County, Me., Medical Association (Lewiston).

Thursday, *August 6th:* Society of Physicians of the Village of Canandaigua, N. Y.

Saturday, *August 8th:* Miller's River, Mass., Medical Society.

Letters to the Editor.

THE INTERNATIONAL MEDICAL CONGRESS.

University of Michigan, *July 27, 1885.*

To the Editor of the New York Medical Journal:

Sir: Please add our names to the list of those gentlemen who have already declined to serve as officers in the organization of the International Medical Congress as now arranged by the second enlarged committee of the American Medical Association at their recent meeting in Chicago. In taking this step we do not intend to criticise the committee for their action. On the contrary, we think that, handicapped as they were, they did their work remarkably well. But we do object to the action of the American Medical Association at the New Orleans meeting in introducing into the question of the organization of a congress for scientific work an element that has no more pertinency to such a purpose than the matter of a man's religion or his politics. Very respectfully, etc.,

E. S. Dunster, M. D.,
Henry Sewall, Ph. D.

THE INTERNATIONAL SANITARY CONFERENCE AND THE DISINFECTION OF RAGS.

To the Editor of the New York Medical Journal:

Sir: In justice to me, I trust that you will publish the following letter, which I have just written to the "New York Times," in your next issue.

"To the Editor of the 'Times':

"Sir: In your issue of July 22d, under the heading 'The Importation of Rags,' I find the following:

"'The frequency with which inaccurate statements have been made concerning the disinfection of imported rags is somewhat extraordinary. Several days ago the "Times" called attention to a letter from Rome, published in a Philadelphia medical magazine, which purported to give the report agreed to by the Committee on Disinfection appointed by the International Sanitary Conference. The letter in question contained the following clause:

"'"V. Disinfection of merchandise and of the mails is unnecessary (steam under pressure is the only reliable agent for the disinfection of rags—*les chiffons en gros*)."

"'The "Times" suggested that probably the words were interpolated by the writer of the letter. A few days thereafter Dr. George M. Sternberg, the American delegate to the conference, and the same gentleman who was employed as an expert by Health Officer Smith to make some tests of disinfecting processes in Brooklyn, sent a note to the "Times" denying that the writer of the letter had interpolated the words in question. A gentleman in this city who is interested in the importation of paper stock wrote to Dr. Koch at Berlin for definite information on this point, and yesterday he received a cablegram stating that no such words as those quoted in parentheses appear in the report of the committee.'

"The subscriber has nothing to do with the fight between the paper manufacturers and the health officers who insist upon the disinfection of rags from cholera-infected countries, but must request space in the 'Times' to defend himself from the grave charge made in the above-quoted paragraph.

"What the gentleman *interested in the importation of paper stock* wrote to Dr. Koch I do not know, but that Dr. Koch should deny that the words referred to are a part of the report of the Committee on Disinfectants is incomprehensible, and can only arise from some misunderstanding on his part.

"I inclose herewith a copy of the report of the Committee on Disinfectants which was printed in Rome and distributed to all of the members of the Conference. The correspondent of the Philadelphia medical journal referred to has given a very good translation of Article V, which in the original is as follows:

"'V. La désinfection des marchandises et des colis de poste est superflu (La vapeur sous pression serait le seul moyen si on voulait désinfecter les chiffons en gros.)'

"The same wording will be found in the report of the committee as adopted in *procès-verbal* No. 10, page 3; also in the *Relevé des conclusions*, page 16.

"A copy of the proceedings, printed in French and brought by myself from Rome, is on file in the office of the Hon. T. F. Bayard, Secretary of State, and another copy in that of the Surgeon-General, U. S. Army."

George M. Sternberg, *Major and Surgeon, U. S. Army, Delegate to International Sanitary Conference.*

Proceedings of Societies.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-first Annual Session, held at the Pequot House, New London, Conn., Wednesday and Thursday, July 15 and 16, 1885.

(*Concluded from page 105.*)

Two Cases of Congenital Paresis of the External Rectus were reported by Dr. Harlan, who also exhibited and described Borek's sphero-cylindrical lenses.

The Removal of a Piece of Steel from the Lens with the Electro-Magnet.—Dr. J. L. Minor, of New York, reported a case in which the shank of a strabismus-hook was touched to an electro-magnet, thus making it a magnet. The extremity of the hook was then carried into the lens, and the piece of steel at once attached itself to it and was removed. Thirteen days later the eye had recovered from the operation. The lens had not yet been removed.

Removal of an Epithelioma of the Eyelid by Applications of Benzol and Calomel.—Dr. A. Mathewson, of Brooklyn, reported the case of O. D., a laborer, fifty years of age, who was seen October 3, 1881, with a tumor on the right lower lid. This first appeared as a warty growth three years previously. Of late it had been rapidly growing, and presented a raw granulation surface. Careful examination by an expert showed it to be undoubted epithelioma. It was treated by frequent dustings of calomel, after brushing the surface with benzol. The tumor entirely disappeared until a few months ago, when a granular spot appeared at one edge of the site of the former growth. This disappeared under a renewal of the same treatment.

Lipomatous Ptosis.—Dr. H. S. Schell, of Philadelphia, reported four cases of ptosis from excessive accumulation of fat in the upper lids. The excessive fat was removed through a horizontal incision. The smallest amount taken away was thirty-five grains, the largest seventy-one grains. The levator regained power in from one to four weeks. In one case it was necessary to repeat the operation.

The Pulsating Variations of Intra-ocular Tension as measured by the Manometer.—Dr. Lucien Howe, of Buffalo, N. Y., exhibited the double manometer described by Grasser and Holzke. In this there was an imperfection in the trocar

which was rather complicated and liable to get out of order. An improvement was accordingly suggested in having a stop-cock attached to a needle of the hypodermic syringe, and this the writer found to serve the purpose much better than any other. The animal best adapted to this class of experiments was the cat, on account of the deep anterior chamber.

In the earlier experiments with the manometer it was noticed that the intra-ocular tension varied with the heart's action. In addition to this, the writer called attention to the fact that these variations in the pressure as indicated by the manometer corresponded to pulsations which could be seen with the ophthalmoscope in the vessels in the interior of the animal's eye. In other words, if the same thing held in the human subject, we must infer that, when pulsation was seen in the interior of the eye, there was also a variation of intra-ocular tension, although not enough to be detected by the touch or by an ordinary instrument. This connection between pulsation and pressure was a demonstration of the cause of venous pulse in the eye as explained by Donders. It was also observed that after the introduction of the needle there was at first considerable pulsation, but after a short time this ceased, the eye evidently adjusting itself to the unusual condition. The experiments referred to were made in the laboratory of Prof. Zunzt, of Berlin.

The Extraction of Chips of Iron from the Interior of the Eye.—Dr. H. Knapp reported nine successive cases in which the electro-magnet was used for this purpose.

These cases were operated on during the past three years and a half. In two the chip of iron was located in the iris, in one for two days, causing inflammation, and in the other for seventeen years, remaining quiet until recently. Both were successfully removed without injury to the eye.

In the seven remaining cases the foreign body was in the vitreous, had produced cataract, and could not be seen. In three cases the attempt to extract them with the magnet failed, and the eyes had to be enucleated. In four cases the chips of iron were brought forth at the first, second, or third introduction of the tip of the magnet. In all these four cases the recovery was uninterrupted. All four were still cataractous. In two the form, size, and tension of the globe were not changed, and the perception of light was good over the whole field. In the two others the globe was slightly smaller and softer and the field of vision defective, corresponding to the wound made for the extraction of the foreign body. There was no irritation in any of the four eyes as long as they were under observation.

The Actual Cautery in Destructive Corneal Processes.—Dr. Knapp cited a number of cases in which its use had been of service, and he considered it a valuable measure.

Thursday's Proceedings.

Pneumophthalmos, or Air in the Vitreous.—Dr. W. F. Mittendorf, of New York, reported two cases, the first of which was that of a young blacksmith who was wounded by a piece of iron penetrating the sclera and lodging in the vitreous. The foreign body, surrounded by a clot of blood, was found at the bottom of the eye. Behind the lens and a little above it, three air-bubbles were seen by means of the ophthalmoscope. These appeared to be of the size of a small pea, the smallest about as large as a rape-seed. They closely resembled the air-bubble as seen under the microscope, their centers being bright and the outlines well defined, and surrounded by a sharp, black border. Their recognition was not difficult. The foreign body could not be removed with the magnet, and it was decided to allow it to remain. The eye was carefully bandaged, and the day following it was found that the air-bubbles had united and were located at the posterior pole of the lens, the patient having remained quietly on his back some time before the examination. While he was in the upright position the air began to rise slowly until it reached the upper part of the vitreous chamber. During this trip the bubble looked oval and decidedly pointed at its lower portion, resembling oil-globules as they are seen ascending in water. Forty-eight hours after the accident every trace of the air-bubbles had disappeared.

The second case was the result of a drilling accident. Quite a large piece of stone or iron had perforated the sclera at the lower and outer part of the eye. In the semi-transparent vitreous an air-bubble of the size of a hemp-seed could be seen distinctly.

In order to determine the exact appearance of air in the vitreous, the writer experimented upon rabbits' eyes. Four of them had air introduced into the vitreous humor by means of a hypodermic syringe, and four were subjected to the introduction of oil, also by means of the hypodermic syringe. Nearly all these experiments were successful. The difference between the air- and the oil-bubble was so marked that they could be readily diagnosticated by means of the ophthalmoscope. The latter were more highly refractive, heavier in appearance, and the contour decidedly darker than the air-bubbles, which were entirely colorless.

The conclusions reached by the author were as follows: 1. The entrance of air into the vitreous body could occur only after a part of the contents of the vitreous chamber had escaped. 2. It was favored by the entrance of a foreign body, which made a large, gaping, irregular wound of the sclera. 3. In order to allow air to enter the vitreous, this must either be quite fluid or its anatomical arrangement must have been disturbed by the entrance of a foreign body, or the air must have been attached to the foreign body and carried with it into the eye. 4. The air in the vitreous humor appeared like an air-bubble as seen under the microscope; it was more or less round, highly refractive in the center, and had a sharply defined black outline. 5. Oil-globules in the vitreous presented a similar appearance, but they looked heavier and were not perfectly colorless, and their outlines were darker; they were also more glittering in the center. 6. Air-bubbles would be absorbed completely within two or three days; their presence was not a source of great danger to the eye. Oil-globules lasted longer, but they were likewise non-irritating.

A Case of Tubercle of the Iris.—Dr. Myles Standish, of Boston, reported the case of a girl, fourteen years of age, who came under his observation with an eye trouble which had existed four weeks. There had not been much pain or photophobia. No specific history could be elicited. During the past winter the patient had suffered with intense epigastric pain and ascites. The iris was attached by its pupillary margin to the capsule of the lens, and presented near its ciliary border a growth 2 mm. in diameter, pink in color, with small vessels on its surface. In the course of a month the growth had doubled its size, the conjunctiva and iris remaining perfectly clear. Other growths made their appearance, and, after consultation with Dr. Wadsworth, the eye was removed at the Massachusetts General Hospital. Examination after enucleation showed the vitreous, retina, and choroid to be normal. The lens was somewhat opaque. The iris was very adherent to the capsule of the lens along its pupillary border, and also beneath the entire area of the principal growth. The largest mass sprang from the surface of the iris near its ciliary border, and at its base was 2·5 mm. in diameter and 2 mm. in height. At the top its diameter was 4 mm. This was apparently due to the pressure of the growth against the cornea. There were three other growths, but none of them involved the ciliary body, or even the ciliary border of the iris. The microscopical examination showed the presence of giant cells and of tubercle bacilli.

Dr. Knapp had seen growths presenting exactly the same appearance which had disappeared under treatment with mercury, even where there was no evidence of syphilis. He had never felt warranted in making the diagnosis of tubercle in such cases, although the presence of the tubercle bacilli in this case would seem to confirm the diagnosis.

A Case of Congenital Coloboma of the Iris, Choroid, etc., was reported by Dr. C. J. Kipp. The patient was a woman sixty-nine years of age. She was first seen four years ago. There were at that time no inflammatory symptoms, but a small triangular coloboma of the iris was found exactly in the vertical meridian. The tension was above normal. The patient had never seen with this eye, but it had never given pain. Four years later the patient was again seen, and the eye presented the signs of inflammatory glaucoma. The pain had prevented sleep for many weeks. The eye was enucleated and healed promptly. There was also found a large ectasia of the sclerotic, and over this the choroid and retina were wanting. The ectasia extended close to the optic papule. There was also a deep, kettle-shaped excavation of the optic nerve.

Coloboma of the Choroid on the Temporal Side.—Dr. S. D. Risley, of Philadelphia, reported the case of a young physician who consulted him for asthenopia. There was a considerable degree of myopia in the left eye. In the right eye vision was much diminished. The ophthalmoscope showed a large hiatus in the choroid on the temporal side, the depth of which was 3 D. There had been no pain. The speaker thought that these cases were comparatively rare.

Gray Degeneration of the Optic Nerve with Abnormal Patella Tendon Reflex.—Dr. William F. Norris made an elaborate review of the literature of the subject, and gave the results of his observations in cases in which the patella tendon reflex was increased or diminished. He described three cases of gray degeneration associated with tabes dorsalis which had come under his observation. While he did not hold that this symptom indicated beginning tabes dorsalis, yet it was a danger signal calling for rest of the brain and cord, with attention to improvement of the general condition.

A Case of Double Optic Neuritis and Ophthalmoplegia from Lead Poisoning complicated with Typhoid Fever.—Dr. O. F. Wadsworth reported the case of a boy nine years of age who had suffered from obscure febrile symptoms for several weeks, and movements of the left eye had been observed to be imperfect. When first seen by Dr. Wadsworth there was pronounced optic neuritis in both eyes. The rest of the fundus was normal. Vision was much diminished. No lateral movements of the left eye could be made, and movement downward was impaired. The outward movement of the right eye was defective. The probable diagnosis was tumor in the region of the pons.

The movements of the eyes became still more impaired and vision sank. The boy developed distinct symptoms of typhoid fever. The spleen and liver were both enlarged. Lead was found in the urine, and the diagnosis of tumor was then abandoned. The treatment was with iodide of potassium. The general condition gradually improved; the neuritis passed into atrophy, leaving too little vision to count fingers. The movements of the eyes were completely restored, and the lead disappeared from the urine. The cause of the lead-poisoning was found to be the presence of a piece of lead pipe in the cistern from which the drinking water was obtained.

Olive-Oil as a Menstruum for Dissolving Cocaine for Application to the Eye.—Dr. Joseph A. Andrews said that the plan of dissolving cocaine in oil seemed to insure a longer contact of the remedy, and a smaller quantity was required to effect anæsthesia—two qualities of special advantage in operations on the eye. Neither the salts of cocaine nor those of atropine were soluble in olive-oil; but both alkaloids dissolved readily in the menstruum without the addition of an acid, it being only necessary to expose the solution for a few minutes to a gentle heat in a water bath.

Enucleation of the Eye for Glaucoma precipitating Glaucoma in the other Eye.—Dr. David Webster reported a case, the patient being a man of fifty-four, the subject of glaucoma absolutum. He complained of periodical obscurations of vision in the good eye, and there was no limitation of the visual field. As he was of dissipated habits, he was advised to live properly. A week or two later he returned, stating that he had had a worse attack. There was detected an excavation of the nerve in the good eye. The glaucomatous eye was now removed. Two days later acute glaucoma appeared. An iridectomy was performed, and he recovered in a week or two, with no cupping of the disc and no limitation of the field.

Quinine Amaurosis.—Dr. E. Williams reported two cases. In the first case a man took about one ounce in the course of four days. This produced total blindness and deafness, but in six weeks he could see as well as ever. The hearing had never completely returned, although the quinine was taken eight years ago. The field of vision was concentrically contracted in both eyes. The optic discs were very white, the caliber of the arteries and veins was reduced, and the smaller capillaries could not be seen.

The second case was that of a boy of fourteen, who had received large doses of quinine, the exact amount not being known. He was totally blind for four days. When examined, the sight was much diminished, the atrophy of the optic discs was extreme, and there was great contraction of the field of vision.

A Means of Measuring the Amount of Anæsthesia from Cocaine.—Dr. Lucien Howe exhibited the drawing of a kymograph, which he had used for this purpose. The use of the instrument was based on the fact that irritation of a sensory nerve was followed by a rise of blood-pressure. The instrument was connected with an artery, and the conjunctiva was irritated. Cocaine might then be applied, and the results on the blood-pressure compared.

Officers for the Ensuing Year.—President, Dr. W. F. Norris, Philadelphia; Vice-President, Dr. Hasket Derby, Boston; Secretary and Treasurer, Dr. O. F. Wadsworth, Boston; Corresponding Secretary, Dr. J. S. Prout, Brooklyn.

New Members were elected as follows: Dr. Charles A. Oliver, Dr. Edward Jackson, and Dr. B. Alexander Randall, Philadelphia; Dr. D. Pope Walker and Dr. William O. Moore, New York; Dr. Frank G. Capron, Providence; Dr. S. M. Burnett, Washington; and Dr. William T. Bacon, Hartford.

The next meeting will be held at New London, the third Wednesday in July, 1886.

CLINICAL SOCIETY OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Meeting of March 7, 1885.

Dr. F. R. Sturgis in the Chair.

Syphilis.—The Chairman read a paper on this subject. [See page 120.]

Dr. G. H. Fox did not consider that syphilis was the frightful disease that the text-books would have us believe. He also thought the results of its treatment by mercury much overrated, and considered that this drug could be dispensed with without involving any risk to the patient. The value of a remedy in the treatment of any special disease could only be determined when

the opportunities of studying the natural history of the trouble had been taken advantage of, and he did not believe that this was the case with the mercurial treatment of syphilis. Many persons were, too, greatly adverse to mercury, and therefore it had been the custom for a number of years in the New York Dispensary to ask the patient if he objected to its use, and if the reply was in the affirmative, as it often was, they considered that they were authorized in omitting it altogether, taking the liberty of thus carrying out an experiment with the consent of the individual; and this practice in his hands had been free from bad results. He considered that the average case of syphilis was benignant in character, and, given average good health, previous to the inception of the disease, did not believe that it would produce the ravages ascribed to it. He did not care to say that mercury was useless in these cases, but thought it was better to rely upon tonic and hygienic measures than upon the drug alone, and he felt convinced that many patients recovered under this mode of treatment. He knew of several old men who had undoubtedly contracted the disease in their youth and who had completely recovered without the intervention of mercurial treatment. He also thought that when mercury was used the dose should be much smaller than the one usually employed, considering that half a grain of blue mass would accomplish all that could be gained with one to two grains. The treatment of syphilis should no more be based upon a routine plan than the treatment of scarlet fever, and, just as there were some cases of the latter affection so mild as to need no treatment, so there were cases of syphilis that could fall under the same category. It was absurd, in his opinion, to continue a mercurial treatment for two or three years in cases that were really so mild that, if left to themselves, they would end in recovery; but in deference to custom he usually did continue the treatment for six months after the symptoms had disappeared. His opinion was, however, that in the severer forms it was better simply to treat the symptoms as they arose. In the stage of efflorescence iodide of potassium had no curative value and should never be continued for a long period. He considered that great harm could be done by giving too much of this drug, as several physicians had reported cases where the symptoms of iodism were substituted for those of syphilis. Where no good results were noted from the use of this remedy harm was almost sure to follow, and then it would have been much better had the money thus thrown away been expended in beefsteak and country air.

Dr. William H. Porter remarked that his conclusions, deduced from both clinical observation and experience in the post-mortem room, were that, in a very much larger proportion than was commonly supposed to be the case, of the patients suffering from diseases of the viscera, an initial syphilitic lesion could be discovered. This was peculiarly the case with the cerebro-spinal system, lungs, liver, and kidneys. He was decidedly in favor of mercury in the treatment of this affection, but did not consider very large doses of the iodide necessary. It was very necessary to give calomel or podophyllin frequently, however, in order to have a free and frequent action upon the liver; he considered this particularly important in the inherited forms. He was in favor of combining the mercury and iodide of potassium, and had found that the iodide of ammonium had an effect, apparently not from any inherent curative power, but because it seemed to act in very much the same way as trituration did with calomel, increasing the power of the combined drugs so that the same result was obtained from smaller doses than when the ammonium was not employed. He had obtained quite as good results from one sixteenth of a grain of the biniodide of mercury, fifteen grains of the iodide of potassium, and five grains of the iodide of ammonium at a dose, when sixty, eighty, or even one hundred grains of the saturated solution of the iodide of potassium had failed. If by combining these substances a small dose would effect the same result as the larger one, it was of course better.

Dr. G. B. Hope had seen cases of so-called cured syphilis where the initial lesions had disappeared and the later symptoms had been absent for years, but where ulcerations of the throat and larynx existed of such a character as to be at once serious and dangerous. These cases yielded more readily to treatment when internal medication with mercury and the iodide of potassium rather than topical applications was employed. He had found that iodoform could be elegantly prepared, and, when combined with morphine powder and used as a local application, gave great relief.

Dr. D. B. St. J. Roosa remarked that, as his chief interest lay rather in general medicine and surgery than in the specialty into which the circumstances of his life had directed him, he preferred speaking on the subject from that standpoint. He had been particularly interested in the discussion because it indicated that the therapeutics of syphilis was approaching a standard of correctness which was hardly comparable with the iron-clad notions which formerly obtained regarding the efficacy of drugs in the treatment of this affection. If it should ever be his misfortune to be inoculated with this disease, he would prefer to put himself into the hands of a good cook and housekeeper, with country air and plenty of exercise, to trusting to the empirical remedies applied by many physicians whom he could designate. The homœopathic theory, which considered all disease a beast, to be hunted out by some other beast, was not even true in syphilis; neither was it true, on the other hand, that this affection could be successfully combated without recourse to drugs of any kind, for was it not apparent to every one what remarkable results were obtained by the use of iodide of potassium in the late ulcerations of the fauces and throat? In ophthalmology, however, if the patients were in an infirmary, where they could have good and nutritious diet and proper bathing facilities, drugs could be dispensed with, but even then we should not forget that the character of syphilis differed in different individuals. The late Dr. Willard Parker had been accustomed to say, "Study the history of a family before you say a patient is going to die."

The Chairman would recall the instance of a medical gentleman who, troubled with a recurring ulcer of the cornea, had consulted both of them as to whether or no he had syphilis, and it was well, perhaps, to remember that we never found this ulceration in the acquired, although it was very common in the hereditary form.

Dr. W. O. Moore said that at the New York Eye and Ear Infirmary during the past fifteen years one per cent. of all the eye diseases could be traced to a syphilitic origin. Iritis was the most common, forty-five per cent. of those inoculated being affected in this way. Next in the order of frequency was paresis of the ocular muscles, sixty-five per cent. of all these cases being of a specific origin. The muscles most commonly affected were those supplied by the third, sixth, fourth, and fifth cranial nerves. Thirteen per cent. of all the cases of retinitis were specific. The rarer forms in which this infection exhibited itself were: conjunctivitis, nine cases; ophthalmitis, three cases; chancre of the eyelid, two cases; mucous patch of the palpebral conjunctiva, two cases; condyloma of the lid, one case. Hereditary syphilis was the ætiological factor in forty-four per cent. of all the diseases of the cornea, and the clinical fact was well known that the cornea was not affected by the acquired variety except through ulceration propagated by contagious inflammation, as in mucous patches of the lids; but in the hereditary variety it was by far the most common eye lesion.

Dr. Culver considered the Turkish bath a very valuable ad-

juvant to mercurial treatment. In Vienna he had seen from eighteen to twenty-four inunctions effect a cure.

Dr. Porter said that he had never had any personal experience with the Turkish baths in the treatment of these disorders, but it was a well-known fact that all syphilitic processes were removed by increasing the oxidation which consequently caused the excretory organs to be overworked and their epithelium to become cloyed, so to speak. He thought the bath would tend to free them from this effete material, and would be of great aid to the system generally; for the same reason he considered free purgation essential.

Dr. J. M. W. Kitchen had a patient who refused to be treated with mercury internally, and asked the chairman by what method it could be applied by the spray.

The Chairman replied that the usual spray was a preparation of half a grain of the bichloride of mercury to four ounces of water. This was not irritating, but was not in general use, astringents being usually preferred.

Dr. W. N. Leszynsky had used the hypodermic injection of a solution of the corrosive sublimate in four cases, in doses of a thirty-second of a grain, with a little morphine, combined with glycerin and water. The injections were given in the muscles of the back once daily, and in one case thirty-two, in another twenty-four, and in the others between twenty and thirty punctures were made without the occurrence of a single abscess. In every instance there was some burning pain following the injection, but the discomfort was of but temporary duration, and in each instance care was had that the injection should be at least half an inch from the place where the preceding puncture had been made. In all the cases there was a clear syphilitic history, and two of the patients, while under observation, had an eruption, with the fever and headache of the secondary stage. He had never found that the iodide disagreed with an empty stomach, and had been in the habit for some years of giving it before meals, sometimes, however, dissolving it in a little milk. Where a tonic treatment was also necessary, he would give the iodide before and the tonic after meals.

Dr. Charles Henry Brown considered that in by far the largest number of cases the recoveries from syphilis took place in the primary or secondary stage, and that only in the minority of cases did it provoke destruction of tissue and proceed to the exhibition of late phenomena. He did not doubt that many a practitioner had seen suspicious sores that were indurated, accompanied with swollen inguinal glands and other suspicious circumstances, but where the history of contagion was absent, and yet the symptoms were strong enough to lead the ordinary observer to diagnosticate the affection and declare that the patient was suffering with the primary lesions, which diagnosis would not be doubted until the time for the appearance of the secondary lesion had passed without the vestige of any cutaneous blemish.

All writers upon this subject had so emphasized the fact that the secondary lesions had to appear, that, if for any reason they did not show themselves, the suspicious sore would be allowed to pass unchallenged and be considered as simply a local, unimportant affair. This might or might not be the case, for he considered that many primary lesions never went beyond the first stage and were not followed by any secondary phenomena. The chairman had laid it down as an axiom that the primary lesion required only local treatment, and that only after the appearance of the secondary symptoms were we to adopt heroic treatment. He did not doubt that many of those present had seen patients run through their secondary syphilide as easily and as unconcernedly as a child with chicken-pox, provided they did not know what they had and were in good physical condition. The vast majority of acute diseases were treated upon an expectant plan, and we all knew that we could not compete with Nature's modes of treatment; in fact, we could only hope to assist her in her plans. He had been in the habit for two years past of treating this affection, both in its primary and in its secondary stages, without recourse to mercury, simply keeping an eye upon its progress, and when disturbing elements, such as mucous patches, tonsillar or naso-pharyngeal inflammations, etc., appeared, he treated them with local applications, which in the vast majority of cases he found to be quite sufficient. He did not wish to be understood as deprecating the use of mercury, as he considered it one of the giants of the materia medica, and thought that it undoubtedly often did all that was alleged of it, but he was inclined to the belief that its action was often, in this complaint, confounded with the natural limitation of the disease. He also objected to the term specific as applied to the action of drugs, as he thought it implied something mysterious and something not fully understood; if it was necessary to make use of any term, he considered "unknown action" far preferable. The action of mercury was not, however, unknown, and its action in syphilis, as the chairman had remarked, was the same as in any other case. He fully agreed with all this, but thought that we should not stop without adding that it failed quite or nearly as often as it was successful. Was it not possible to call to mind case after case that had not been controlled by mercury? The severe types of this disease needed all that Dr. Roosa recommended, and, if possible, even more. The dietetics and hygiene of syphilis had never received the attention that they deserved, and yet we had to look in this direction for the cure of the severe and otherwise unmanageable cases oftener than to any other method of treatment. The use of the Turkish and Russian baths, electricity, exercise, and tonics should be encouraged in every case. The banishment of syphilophobia, which had as potent a power in retarding recovery as any other agent in the disease, should always engage the attention of the physician. The drug which the speaker preferred was iron. If pain, ulceration, etc., complicated the course of the disease, they should receive local treatment in the shape of oleates and plasters, and calomel dusted on the surface of the ulceration. He considered this method of administration preferable to giving the drug by the stomach, as its action was exerted directly upon the diseased structure. The late phenomena of syphilis were not so self-limited in duration, and demanded more vigorous methods of treatment than the primary, but care had to be exercised in these cases to improve the constitutional condition, and to place the surroundings in as perfect a hygienic condition as possible. He did not consider iodide of potassium capable of exerting any harmful influence upon the constitution, and, in his experience, although it did not work rapidly in lesions of the nervous system, it was wonderfully efficacious in dissipating the late lesions of the disease. Large doses, however, were essential, and he had frequently seen patients who took two hundred grains three times a day without discomfort. In giving such large doses it was necessary that it should be lavishly diluted, two hundred grains to the pint, and from fifteen to twenty minutes occupied in its consumption. Under these circumstances it mattered little whether or not it was taken on an empty stomach. He had never seen any bad effect from these doses, unless the patient refused to take a large amount of water. In the department of nervous diseases they were not in the habit of looking for much improvement until the patient reached one-hundred-grain doses. In cases where there was considerable sclerosis of nerve-tissue the iodide was alternated with nitrate of silver, and in such cases it was noticed that when the patients returned to the use of the iodide the effects were often more marked than in the first instance.

Dr. T. E. Satterthwaite then presented the histories of

three cases which illustrated some unusual symptoms following the internal administration of the iodide of potassium.

Case I. *Following the Administration of the Iodide of Potassium in Moderate Doses.*—On March 6, 1882, I was called to see J. C., who had previously been brought to me through my attendance upon members of his family. I found him suffering from agonizing headache, chiefly of the vortex, and that he had taken large doses of quinine, which had greatly aggravated the symptoms. It was known to me that he had acquired syphilis fully twenty-five years before, that he had contaminated his wife soon after marriage, and that, after many years, she had only succeeded in bringing into the world a delicate boy, who had now arrived at maturity, but was phthisical. I had also been informed a number of times previously that he had refused to take antisyphilitic remedies, because he disbelieved in doctors and medicines. In the present extremity, however, he consented to follow out my recommendations. He was immediately put upon the use of iodide of potassium, in thirty-grain doses, three times daily. After the third day an amelioration of the symptoms was noted, and, as the patient exhibited no phenomena of iodism, the doses were doubled, when almost immediately coma, with paralysis of the upper and lower extremities, set in. In fact, all the indications pointed to cerebral compression. The iodide was immediately stopped, consciousness returned, and with it the paralysis disappeared. With a view of ascertaining whether the iodide was to be credited with producing these remarkable conditions, it was again given in drachm doses, and was followed, as before, by coma, which also disappeared upon the discontinuance of the drug. The late Dr. J. L. Little saw the case with me in consultation during both attacks of coma. Under the iodide, in ninety-grain doses, daily, the patient fully recovered, and was able to resume his occupation.

Case II.—For the notes in this case I am indebted to my friend and colleague, Dr. Porter. J. N. P., thirty-three, England, contracted syphilis in 1870, eight years before the present attack. A year later he married, and his wife subsequently had several miscarriages in succession. The attack here described occurred in May, 1878, and began with a severe cephalalgia. On June 3d following he began to be aware of some paresis of the left side, and had left ptosis. His mental faculties began to deteriorate at the same time. A little later, June 13th, he was put upon the "mixed treatment," to which the iodide of ammonium was added; but, showing no improvement, he was given, June 24th, calomel, one forty-eighth of a grain, every fifteen minutes, which failing, the iodide of potassium, in fifteen-grain doses, was added on the 29th. Through some mistake it was taken at first every fifteen minutes, and how long it was continued at these intervals can not be judged; but two days later, July 1st, he became comatose, and when first seen could not be aroused. The pupils were contracted, sensation over the body was not abolished, the pulse was 80 and strong, and the respiration was 24. Subsequently the coma lightened slightly, and he could be aroused when shaken. Later on consciousness returned fully, and simultaneously there was dilatation of the pupils. As it was not known that he had taken a large amount of the iodide, it was again ordered, and was given, presumably, in fifteen-grain doses every fifteen minutes, in conjunction with the mixed solution before mentioned. On the following day the patient had another attack of coma, and then only was it discovered that these extraordinarily large doses had been given. They were immediately stopped, and the iodide was continued in moderate and gradually decreasing doses until July 7th. He received one sixteenth of a grain of the biniodide of mercury, with ninety grains of the combined potassium salts, six times a day. This amounted to a dosage of two hundred and eighty grains of the iodide of potassium, and the same number of grains of the iodide of ammonium per diem. This was continued without intermission until the 13th, when he was discharged from the hospital greatly improved. In this instance there was no renal lesion, nor was the coma attributable to anything but the potassium salts. It was impossible to determine the amount of the iodide given daily in this case, but it was evidently more than a drachm.

These two cases appeared to represent what had been called by Wunderlich the narcotic symptoms of iodism, among which he mentioned dizziness, diminution of intellectual power, incoherence of ideas, paresis, and even wild delirium, though neither he nor any other writer, so far as the speaker knew, had ever fully described the coma of iodism. The nearest approach to this condition appeared to have been noted by Sir Benjamin Brodie, who described the paralysis of iodism.

Stillé cited the example of a man aged fifty-five under the treatment of the iodide of potassium where trembling of the limbs, a feeling like intoxication, an irregularity of motion, and double vision were experienced. Bumsted and Taylor stated that sometimes the iodide caused an oppression in the head, muscular debility, and sluggishness of the intellect. Other symptoms of iodism had been frequently discussed by writers. The amount taken appeared not to be a matter of much consequence, for in certain persons and under certain conditions the iodide would prove poisonous even in very small doses; thus, Stephen McKenzie had known an infant die of purpura after taking two grains and a half of the iodide ("British Med. Journal," 1880, vol. i, p. 626), and the same fact had been noted by Little (*Ibid.*, April 24, 1880), while Phillips ("Mat. Med.," vol. i, p. 64) cited a case in which one grain administered to a syphilitic patient three times a day produced iodism.

Of a different nature is the following example of profuse salivation and respiratory embarrassment, following moderate doses of the iodide:

Case III.—A. J. N., a young man about thirty years of age, consulted me at my office, December 11, 1883. He was then suffering from supra-orbital, infra-orbital, and maxillary neuralgia, with some intra-cranial headache. For his relief I gave him morphine, the bromides, and chloral, but the removal of the pain was finally effected only by large doses of quinine (forty grains a day). In the following month he developed aphasia, difficulty in articulation of labials and sibilants, and loss of memory. On January 25, 1884, he was put upon the use of iodide of potassium, taking twenty minims of the saturated solution three times a day. Almost immediately he began to complain of a sore tongue, on which account the medicine was discontinued, but profuse salivation ensued and continued to the time of his death, February 4th, coma having set in after an apoplectiform seizure. It may be inferred that the cerebral symptoms in this case were not due to the iodide, from the fact that they developed fully a week after the suspension of the drug, while it is a matter of general belief, on the other hand, that these symptoms disappear on the withholding of the drug. It is equally true in this instance that the soreness of the mouth and salivation, the coryza, the swelling of the face, and the symptoms of obstruction of the larynx gained in intensity between the inception and death; and it is also noteworthy that the paralysis, at least from mercury, is not always arrested by the suspension of the remedy. There was also marked fœtor, as in mercurial salivation. The patient had no renal or cardiac disorder. Dr. J. A. Hegeman, Dr. H. B. McCarroll, and the late Dr. J. L. Little saw the case with me, and it was regarded as singular that the salivation was not arrested, as no mercury had been previously given. Claude Bernard, after taking iodide of potassium, failed to find it in the urine twenty-four hours after, while three weeks later it could be detected in the saliva (Phillips, "Mat. Med.," vol. i, p. 62). It may have been true, therefore, in this case, as it was agreed in consultation that death was due to causes independent of iodism.

During eighteen years of the practice of medicine, he had never before seen or known of such a case, although he was constantly using the iodide, often carrying the dose as high as six drachms per diem.

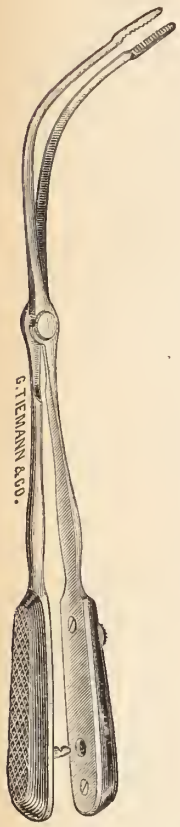
Dr. A. A. Altounyan said that in Turkey he had seen the Turkish bath used in the treatment of this affection. It was usually taken two or three times a week, the patient remaining in the bath for three or four hours at a time and drinking from seven to eight pints of water. Sometimes no medicine at al was used, but mercury was usually administered. Sarsaparilla also had a great reputation.

(*To be concluded.*)

New Inventions, etc.

A NEW UTERINE APPLICATOR AND DRESSING FORCEPS.

By C. N. Dixon Jones, M. D.,
BROOKLYN.



In certain cases in gynæcological practice the ordinary methods of cleaning the part and making application to diseased surfaces have proved so troublesome that I have devised the following-described instrument, which has been manufactured by Messrs. George Tiemann & Co., in order to facilitate the performance of the process.

The instrument is a modification of the well-known throat applicator devised by my friend and instructor, the late Dr. Elsberg. It is essentially a forceps provided with a lock similar to the lock of an obstetrical forceps, in order that the blades may be separated, to facilitate cleaning.

The method of using the instrument is as follows: A bit of cotton is rolled into a wad of the proper size, leaving a firmly twisted projecting portion, which is grasped between the teeth of the forceps without springing the blades; the cotton is then saturated with the appropriate medicament. Thus armed, the instrument is introduced through a speculum and the cotton-point passed through the os tincæ into the uterine cavity, and the medicament brought into contact with the parts to be operated upon.

By using a large wad of cotton, the instrument may be used to clean the vagina of mucus previous to intra-uterine medication, or for making application to the vaginal surface.

After using, the instrument is unlocked, the blades are separated, the cotton is shaken off, and the instrument cleaned.

The instrument in my hands has proved itself of great value, and I can confidently recommend it to the profession.

Miscellany.

Recovery after a Fall of nearly Two Hundred and Fifty Feet.—In the "Bristol Medico-Chirurgical Journal" for June, J. Fenton Evans, M. B., relates the remarkable case of a girl, twenty-two years old, who attempted suicide by throwing herself from the Clifton suspension bridge. After she had partially rallied from the shock, the manubrium of the sternum was found dislocated forward, and there were severe bruises of the buttocks and the back of the thighs. The respiration was feeble, and she vomited fluid containing streaks of blood. Albumin and blood casts appeared in the urine, and there was restless delirium for several days. In less than three weeks the girl had so far recovered as to be able to walk without pain, and there appeared to be no permanent injury beyond slight protrusion at the junction of the first and second pieces of the sternum. The author adds the following remarks:

"The height of Clifton Suspension Bridge above the river at low water is about 250 feet, and the time any weight takes to fall that distance is about four seconds (leaving the resistance of wind, etc., out of the question). The time taken by this girl to fall from the bridge was probably much longer, not only on account of the resistance offered by the 'rather high wind' blowing at the time, but also from the nature of her clothes, which are said to have been inflated from below, and thus delayed the descent. She was also reported to have fallen on the buttocks, which statement was supported by the condition of her clothes on admission and the bruises subsequently discovered. A point of some interest is that the patient's memory is now a complete blank as to what occurred after reaching the bridge, although she can remember setting out from home with the intention of destroying herself in this manner. Of the sixteen persons who have hitherto attempted suicide from this bridge this girl alone has survived the consequences of the act; one other was picked up alive and survived twenty or thirty minutes. As far as the writer knows, no case of survival after a fall from a height of 150 feet has hitherto been recorded; this instance of recovery, after a fall of nearly 250 feet, is probably unique."

Tyrotoxicon (Cheese Poison).—We are indebted to Dr. Henry B. Baker, the secretary of the Michigan State Board of Health, for the following abstract of an important paper read by Dr. V. C. Vaughan at the recent quarterly meeting of the board:

It was well known that cases of severe illness followed the eating of some cheese. Such instances were of frequent occurrence in the North German countries and in the United States. In England they were less frequently observed, while in France, where much cheese was made and eaten, these cases were said to occur very rarely. A few years ago the reputation of a large cheese factory in northern Ohio was destroyed by the great number of cases of alarming illness from eating its cheese. Dairymen knew this cheese as "sick" cheese.

A German author had said that the numerous kinds of soft cheese prepared in small families or on small farms were generally the cause of the symptoms, while it was quite exceptional to hear of symptoms arising from the use of cheese prepared in large quantities. Some two years ago a family in Alpene, Michigan, was poisoned by eating cottage cheese; the cheese which poisoned so many in the State last year was made at one of the largest factories in the State, and by an experienced cheese-maker. The old foul-smelling cheeses, such as Limburger and Schweitzer, had never been known to be poisonous.

The symptoms produced by "sick" cheese, as reported by German and American physicians, agreed quite closely, and were as follows: Dryness of the mouth and throat with a sense of constriction, nausea, vomiting, diarrhœa, headache, sometimes double vision, and marked nervous prostration. In rare instances the sufferer died from collapse. As a rule, recovery occurred in a few hours, or at most after a few days. The symptoms of cheese-poisoning and those of sausage, canned-meat, and fish-poisoning were very similar, though death resulted more frequently from the others mentioned than from cheese-poisoning.

The samples of cheese examined had no peculiarities of appearance, odor, or taste, by which they could be distinguished from good cheese. It was true that, if two pieces of cheese—one poisonous and the other wholesome—were offered to a dog or a cat, the animal would select the good cheese. But this was probably due to an acuteness of the sense of smell possessed by the animal and not belonging to man. Indeed, if a person tasted a cheese, knowing that it was poisonous, he might detect a sharpness of taste which would not ordinarily be noticed.

There was no certain means, aside from a chemical examination, by which a poisonous cheese could be distinguished from a wholesome one. The most reliable ready method was probably that proposed by Dr. Vaughan a year ago, and it was as follows: Press a small strip of blue litmus-paper (which can be obtained at any drug-store) against a freshly cut surface of the cheese. If the paper is reddened instantly and intensely, the cheese may be regarded with suspicion. When treated in this way, any green cheese would redden the litmus-paper, but ordinarily the reddening would be produced slowly and would be slight. If the piece of cheese was dry, a small bit should be rubbed up with an equal volume of water, and the paper should then be dipped in the water. Dr. Vaughan did not regard this test as free from error, but as the most reliable ready means now known. Every groceryman should apply this test to each fresh cheese which he cut. The depth of the reddening of the paper might be compared with that produced by cheese known to be wholesome.

Dogs and cats, at least, were not affected by eating poisonous cheese. This was probably due to the fact that they did not get enough of the poison from the amount of cheese which they ate. The pure isolated poison, in sufficient doses, would undoubtedly produce upon the lower animals effects similar to those produced on man.

Dr. Vaughan had succeeded in isolating the poison, to which he had

given the name tyrotoxicon (from two Greek words which meant cheese and poison). It was a product of slight putrefaction in the cheese, which probably occurred in the vat, as the curd had been known to poison a person. By this slight putrefaction, or excessive fermentation, as it might be called, a large amount of butyric acid was formed, and this, in the presence of the casein of the cheese, was capable of developing a poison. Different samples of poisonous cheese contained different amounts of the poison. The same weight of cheese from one cake furnished three times as much poison as that from another cake. The poison was obtained in long, needle-shaped crystals, which were freely soluble in water, in chloroform, in alcohol, and in ether. The smallest visible fragment of a crystal placed upon the end of the tongue caused a sharp, stinging pain at the point of application, and in a few minutes dryness and constriction of the throat. A slightly larger amount produced nausea, vomiting, and diarrhœa. The poison was volatile at the temperature of boiling water, and for this reason even poisonous cheese might be eaten with impunity after being cooked. The substance had also a marked pungent odor, and through the nose one could obtain sufficient of the volatile poison to produce dryness of the throat. This was true, however, only of the isolated poison. In the cheese the taste and odor of the poison were both modified to such an extent that they would not be recognized, as had already been stated.

The first step in the study of cheese poisoning had now been taken by finding out what the poison was. Efforts would be made to ascertain the means for preventing its formation.

Small-pox in Michigan.—At the same meeting of the Michigan State Board of Health at which Dr. Vaughan's report was read, the secretary submitted a summary of the work done during the quarter ending July 13th. Small-pox had broken out in several localities, among them South Haven, where there had been nine cases and one death. The infection had been brought by a German immigrant who sailed from Bremen on the 12th of April, on the Donau, of the North German Lloyd line. He was broken out with small-pox when he reached South Haven, April 27th, and might have been quarantined *en route*. This was another example of outbreaks which a faithfully executed immigrant inspection service, carried on by the general Government, would put an end to or greatly diminish.

The International Medical Congress and the Profession.—The "Medical News" publishes the following preamble and resolutions adopted in Cincinnati:

"*Whereas*, The recent action of the American Medical Association with reference to the organization of the proposed International Medical Congress was, we believe, detrimental to the best interests of the Congress, therefore,

"*Resolved*, That we, the undersigned, nominated members of the Congress, hereby decline to serve."

	P. S. Conner,	J. C. Reeve,
[Signed.]	F. Forcheimer,	W. W. Seely,
	S. Nickles,	J. T. Whittaker,
	Thad. A. Reamy,	E. Williams.

In addition to the declinations that we have before mentioned, the "News" announces those of the following-named gentlemen: Dr. J. Nevins Hyde, of Chicago; Dr. George M. Sternberg and Dr. R. W. Shufeldt, of the army; Dr. E. Van de Warker, of Syracuse; Dr. William Lee, of Washington; and Dr. J. M. Keating and Dr. George E. De Schweinitz, of Philadelphia.

The same journal publishes the following resolution as having been passed at the recent annual meeting of the American Ophthalmological Society:

"*Resolved*, That it is the sense of the American Ophthalmological Society that the action of the American Medical Association at its late meeting in New Orleans, and of the enlarged committee appointed at that time to make arrangements for the International Medical Congress in overturning much of the carefully planned work of the original committee appointed at Washington for the same purpose, was unwise and not to be defended, unless, possibly, upon technical grounds; and this Society hopes that none of its members will indorse the action of the enlarged committee by accepting official positions at its hands."

The "Pittsburgh Commercial Gazette" publishes the following preambles and resolutions recently adopted unanimously by the Allegheny County, Pa., Medical Society:

"*Whereas*, The American Medical Association, at its recent meeting at New Orleans, has seen fit to rescind the action of the original committee adopted at Washington, to arrange for the meet of the Ninth International Medical Congress, to be held in Washington in 1887, and

"*Whereas*, The new committee in its recent action at Chicago has so changed the arrangements for the meeting of the Congress as to insure its failure, therefore be it

"*Resolved*, That the Allegheny County Medical Society disapproves of the action of the Association at New Orleans and of the action of the new committee at Chicago; and further,

"*Resolved*, That the American Medical Association at its next meeting in St. Louis be advised to restore to the original committee, which was appointed at Washington, full power to make all the arrangements for the meeting of the Ninth International Medical Congress."

The Washington Congress in Danger.—Under this heading, the "Medical Times and Gazette," in its issue of July 18th, says: "Those who have looked forward to taking part in the next International Medical Congress, and have counted perhaps on making personal experience of that friendliness and hospitality of which every English doctor who has yet crossed the Atlantic has brought back such golden report—yes, and not only those, but every practitioner to whom the reputation of his profession is dear—will have read with intense surprise, if not distress, the intelligence we published last week, that the Washington Congress is in imminent danger of falling through. We are sorry to announce that our worst anticipations are in process of realization. The leading practitioners of Philadelphia, many of whom were to hold high office in the Congress according to the list distributed by Dr. Billings some months ago, met together on the 29th ultimo, and decided that, as the changes recently effected in the preliminary organization and rules for the International Medical Congress of 1887 'are inconsistent with the original plan and detrimental to the interests of the medical profession in America, and of the International Medical Congress,' they would decline 'to hold any office whatsoever in connection with the said Congress as now proposed to be organized.' This resolution was signed by thirty of the most distinguished practitioners in Philadelphia, including men like Weir Mitchell, Horatio Wood, Roberts Bartholow, Da Costa, Duhring, Goodell, Minis Hays, Leidy, Pepper, W. Osler, Stillé, Tyson, and Yandell. We hear that a similar movement is on foot in Boston, and that it is quite likely that the most distinguished practitioners in that hub of the universe will follow the lead of their Philadelphian *confrères*. And as some of the leading New York men, including Dr. Jacobi and Dr. Lefferts, who were to have presided over sections, have already been deposed from their places, as adherents of the New Code, while Dr. Bowditch, the most respected physician of Massachusetts, has been struck off the list of vice-presidents for his sympathy with that party, it must be admitted that the 'New York Medical Journal' is probably right in describing the outlook for the Congress as 'gloomy.' We can only hope that the sound sense for which our American cousins are so distinguished will prevail, and that the decisive action of the Philadelphia practitioners will rouse the mass of the profession in America to step in and to decide by overwhelming numbers before it is too late that old controversies shall be sunk, that old ill-feeling shall be buried, and that no one shall be allowed to turn partisan spirit into a ladder for his own elevation at the expense of the reputation and good fellowship of the profession to which he belongs.

"We do not wish, and we hope no one on this side the Atlantic will attempt, to revive the memories of the celebrated dispute on the Codes. We believe that the late Dr. Panum, the lamented President of the Copenhagen Congress, distinctly insisted, when the invitation to America was accepted, that the code question should not be raised; and we feel sure that a very large majority of English and Continental practitioners will refuse to cross the water if this understanding is not rigidly kept to. They will feel, too, that if they go to Washington they can only go as the guests of an undivided profession. A Congress from which the most distinguished representatives of American medicine

were excluded or had withdrawn would not be worth going to as a scientific meeting, while the remembrance of the bitterness and heart-burnings which had attended its organization would rob its social distractions of all their charm. It would be like feasting with a man, while his wife, unjustly divorced, stood in the street watching. We can assure our American readers that in the present case the best English sympathies will be with the wife. The men whom English visitors, if they go, will go to see and hear are the very men who have been elbowed out of the Congress. The scientific success of a Congress does not depend on numbers, but on quality. The profession in America is no doubt rich in numbers, as well as in scientific activity, but it is not so rich that it can afford to play all Europe with only pawns on its side of the board.

"We must add a few lines to explain to English readers how the matter lies. The American Medical Association, a body which includes some three thousand of the forty thousand practitioners in the States, appointed a committee of seven to go to Copenhagen in order to express the desire of the Association that the Congress of 1887 should be held at Washington. The invitation was given in the name of the whole American profession, the Association acting to this extent as its spokesman. It was accepted, and the committee were intrusted with full powers to organize and appoint officers of the Congress. They thereupon added to their original numbers some score of the leading practitioners of the States, and issued the programme which has been distributed far and wide. At a recent meeting of the American Medical Association at New Orleans, Dr. Billings reported on behalf of the committee, but a certain section refused to accept the work done, and claimed that the Association had power to revise it, inasmuch as the committee derived its commission from that body. They succeeded in getting a majority to indorse this claim, and induced the Association to strike off the names that had been added to the committee and to replace them by thirty-eight new men, elected with regard rather to their local distribution than to their scientific attainments. The new committee accordingly, with the exception of the original seven, contains scarcely a name that is familiar to English ears. The question of the competency of the Association to act as it had done was submitted to counsel, with the result that it was declared to have acted quite within its powers. The members of the original committee therefore decided to attend the meeting of the enlarged committee held on June 24th and 25th at Chicago, the reports of which have just reached us.

"At this meeting Dr. Beverley Cole, of San Francisco, was elected permanent chairman of the Organizing Committee, and Dr. Shoemaker, whose name is familiar to us as the active advocate of the use of the oleates known by his name, its permanent secretary. A sub-committee was appointed to revise the rules and preliminary organization of the Congress, published at Washington in 1884, and their report and list of officers was subsequently adopted by the committee. The rules, however, have not yet been published, and we can only say that the first rule was so amended by the committee as to guard against the participation of irregular practitioners in the meetings of the Congress. Besides this, the committee removed from their positions in the Congress some twenty-five men, including Jacobi, Loomis, and Lefferts, who have given up the code of the American Medical Association and retired from that body, but who are still met in consultation by the 'old-coders,' and are members of the New York Academy of Medicine. The committee also entirely changed the executive *personnel*, substituting for men whose names are household words with us others whose reputation has certainly not yet crossed the Atlantic, whatever it may do in the future. It also removed the chairmen of sections from membership in the executive committee, and restricted the membership of the Congress, so far as regards America, to members of the Association, or of State and County societies in affiliation with it, and to others nominated by the executive. After these achievements the committee adjourned to meet in St. Louis just before the next meeting of the Association. The above is a very brief abstract of intelligence derived from the American journals and from our correspondents in the States, and, no doubt, from its very brevity, it will appear somewhat confusing to the English reader. The whole affair will look to him, perhaps, very much like a storm in a teapot. He will perhaps, however, be able to realize the dispute a little more clearly if he can imagine the Committee of Council of the British Medical Association having taken the London Congress of 1881 under its entire control, removed all but a few of the leading London men from any share in organizing the meeting, and allowed no one to participate in the Congress but members of the Association. But even that comparison would be misleading, for the English Association represents at least fifty per cent. of the English profession, while the American Association only contains some seven per cent. of American practitioners."

The "Lancet" on the Congress.—In its issue for July 18th the "Lancet" says:

"The Committee of the American Medical Association, appointed to nominate the list of officers and make the arrangements for the Congress which is to meet in Washington in 1887, has made a preliminary report. It confirms the nomination of Dr. Austin Flint for the post of president. This, we imagine, was never for a moment doubtful, and, as the success of the Congress depends in no small measure upon its president, we are glad to know that this element of success will not be wanting at the Washington meeting. Among the vice-presidents we find the name of Dr. E. Oliver Wendell Holmes [*sic*]. We trust some arrangement will be made for him to give an address at the meeting. The Secretary-General is Dr. John Packard, of Philadelphia, and Prof. F. S. Dennis is nominated chairman of the Finance Committee; these also are excellent nominations. The scientific work of the Congress will be conducted in sixteen sections, one of which will devote attention to the work of Collective Investigation."

[When the foregoing was written the "Lancet" was of course not aware that Dr. Packard and Dr. Holmes had declined to serve.]

The Merritt H. Cash Prize.—The chairman of the Prize Essay Committee of the Medical Society of the State of New York, Dr. W. W. Potter, of Buffalo, writes to us that the committee desires to state that the society offers a prize of one hundred dollars, payable out of the Merritt H. Cash prize fund, for the best original essay on any medical or surgical subject. The conditions are: That the competitors shall reside in the State of New York; that all essays offered shall be either printed or type-written; that each essay shall be designated by a motto on the title-page; that in a sealed envelope, attached to the essay, shall be placed the name of the writer and the corresponding motto; and that all essays shall be sent to the chairman on or before January 1, 1886. Dr. Potter's address is 306 Franklin Street, Buffalo.

Dr. Homans's Laparotomies.—Dr. Homans, of Boston, informs us that, in our summary of the paper he lately read before the Massachusetts Medical Society, we were in error in stating the number of his laparotomies as two hundred and seven, the real number being two hundred and seventy.

The British Gynæcological Society.—Dr. R. Stansbury Sutton, of Pittsburgh, Pa., and Dr. F. C. Batchelor, of New York, have been elected to fellowship in the society.

THERAPEUTICAL NOTES.

Coniine in the Treatment of Cough.—The "Centralblatt für die gesammte Therapie" publishes the following formula:

Coniine hydrobromate, Sugar of milk, each..... 15 grains;
Mucilage of gum arabic, a sufficient quantity.

Divide into forty pills, from two to four of which are to be given daily for nocturnal convulsive cough.

Potassium Iodide for the Prevention of Habitual Abortion.—Goshkevich ("Wratsch;" "Brit. Med. Jour.,") remarks that, although the causes of habitual abortion are obscure, syphilis is the best known of them, and on that ground, notwithstanding the general belief that potassium iodide tends to cause abortion, he advises its employment even when no syphilitic manifestations have been recognized. He gives two cases to sustain his position. The fœtal heart-sounds and movements, which had become almost imperceptible, improved under the use of five grains three times a day, and diminished whenever the administration of the drug was stopped. In each case the full period of gestation was completed.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M. D., NEW YORK.

(*Continued from page 114.*)

ELECTROLYSIS. — When a galvanic current is concentrated within animal tissue by a close approximation of the electrodes, or when, by means of the "polar method" and insulated needles, a galvanic current of high intensity is made to traverse some selected spot upon the human body, there is apt to be a chemical decomposition of the water and salts, and a coagulation of the albuminous elements of the tissue thus acted upon. The salts are then separated into their bases and acids, while the water is simultaneously decomposed into hydrogen and oxygen. The positive pole attracts to it the acids and the oxygen; the negative pole attracts to it the alkalies and the hydrogen. For this reason the insulated needles tend to become oxidized when they are connected with the positive rheophore. They do not become so when attached to the negative rheophore. The free alkalies deposited at the negative electrode are apt, on the other hand, to cause destructive effects upon adjacent tissues. These are greatly in excess of that produced by the oxidation of the metal points of the insulated needles when joined to the positive rheophore.

When we wish to test the strength of the current which we propose to employ for electrolysis, it may be easily done by sending the current through the white of an egg for twenty or thirty minutes. In that time it should coagulate the albumin.

In order to reach the parts upon which we most desire to perform electrolysis, it is often necessary to perforate the skin and the muscles. To do this, needles are employed. They should be insulated with hard rubber, collodion, or shellac, except at their point for one half-inch, and the uncovered part should be gilded, as a rule, in order to prevent its oxidation. They should be from two to five inches long; should be strong enough to penetrate tissues without a liability of breaking; should be as small as is consistent with the current-strength to be employed; and should be so arranged as to enable the operator to adjust them in a handle to which one of the rheophores of the battery may be attached. Ordinary sewing-needles strung on a wire may be employed in treating superficial nævi, tumors, etc., if you lack the instruments specially designed for the purpose. You may shellac them for insulation if deemed best.

It is very important, in some cases, that the insulation of the needles employed be as perfect as possible; and that the tips of the needles be triangular or lancet-shaped, in order that they may penetrate the skin with ease. The needles and handle required can be bought of any manufacturer of electrical appliances.

The battery employed for electrolysis need not be unlike that for ordinary medical purposes. Twenty-four of Grenet's cells will produce a sufficient intensity of current, provided they are freshly filled. Robin's statement that a current of forty-five milliampères is requisite must be based upon a very limited external resistance. It is well to use a battery of greater power than is actually required, so that fresh cells can be added, without breaking the current during the operation, when deemed necessary. Personally, I prefer insulated copper wire for rheophores when performing electrolysis, in preference to the tinsel cords commonly employed for electric applications. They are less flexible than the tinsel cords, but they are vastly superior to them as conductors.

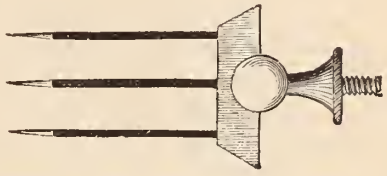


FIG. 37.—ELECTRODE FOR ELECTROLYSIS (with three insulated needles).

Electrolysis has been employed for the following purposes, with more or less success:

1. The coagulation of blood in aneurysmal sacs.
2. The relief of nævi and erectile tumors.
3. The cure of cystic tumors.
4. The cure of goître.
5. The cure of echinococci.
6. The cure of ovarian cysts, and those of the broad ligament.
7. The cure of urethral stricture.
8. The cure of malignant and fibroid growths.
9. The cure of hydrocele.
10. The destruction of the fœtus in extra-uterine pregnancy.
11. The removal of cicatrices, polypi, and other new formations.

Respecting the treatment of large aneurysmal sacs by this method, statistics show that the operation merits more general recognition, as a means of possible cure of intrathoracic and abdominal aneurysms which can not be safely treated by ligation, than it has received. Nine cures out of thirty-seven cases have been collected by Duncan from various sources; and Bartholow has since collected others which have been benefited by it, although not positively cured. In none of these cases, so far as I can ascertain, was the current-strength measured by a galvanometer. There is reason to hope that the operation may become more generally employed when the steps of the procedure necessary to its success are determined with greater exactness. There seems to be a doubt, as yet, regarding the best method both of generating and directing the current, so as to prevent suppuration and secondary hæmorrhage. In two cases of blood-sacs upon the face, intrusted to my care, I have succeeded in consolidating the tumor and effecting its radical cure by this means without suppuration or other complications. I employed the positive rheophore for the needles, and placed the cathode at the nape of the neck in both cases. The duration of the two sittings in each case was about ten

minutes, and twenty-four Grenet cells were employed. I believe that the anode produces the firmest clot; hence the danger of hæmorrhage on the withdrawal of the needles is less than when the cathode is employed. The risk of embolism, as a result of disintegration of the clot, does not seem to be so great as one might at first imagine.

(*a*) (*b*)

Fig. 38.—An Electrode for Electrolysis. The needles are fine and numerous, and are arranged as shown in (*b*). This is an excellent device for effecting the cure of diffused nævi, small glandular tumors, etc.

The employment of electrolysis in cystic tumors of the neck, the ovaries, and the thyroid gland, has been resorted to by many experimenters of note. Among these may be mentioned Althaus, Amussat, Ultzmann, Clemens, Semeleder, and others. Some of the cases reported seem to point toward this method of treatment of these diseased conditions as potent and comparatively devoid of danger if properly carried out.

The *treatment of urethral stricture* by electrolysis I have always heretofore combated—chiefly because I think it less safe and far less certain than gradual dilatation. I must confess, however, that I have had no personal experience in the electrical treatment of stricture; and that my prejudices may be more or less without foundation. My perusal of the reported cures by this method has not, as yet, carried to my mind a conviction of my error. The method seems to me to lack precision, which should, to my mind, form the basis of all surgical procedures within that canal. I am having made for me some modifications of urethral electrodes which I believe will insure greater precision than any yet devised; and I propose to give them a thorough trial.

Ordinary *cases of goître*, and the *enlargement of the thyroid gland which accompanies Basedow's disease*, have been cured by electrolysis. Rockwell and Butler have reported some astonishing results in the treatment of exophthalmic goître by galvanism of the thyroid gland. Rockwell places the cathode over that body and the anode over the solar plexus, combined with the employment of the anode in the auriculo-maxillary fossa and the cathode over the cilio-spinal center (cervical segments of the spinal cord) at each sitting. His cases of reported cure required from fifty to sixty-nine sittings. Needles were occasionally employed upon the goître. This treatment was supplemented by the use of iron, zinc, digitalis, and ergot; and a restricted diet, with instructions regarding the necessity of the repression of the emotions and passions, was enforced.

The *arrest of extra-uterine pregnancy* by electrolysis, and also by shocks transmitted through the sac from Leyden jars charged with static electricity, constitutes, perhaps, one of the most successful and remarkable contributions to medicine. The former method has proved the most reliable. Needles are inserted into the sac and a current is sent through the fœtus of sufficient intensity to destroy life.

The *treatment of cancer* by electrolysis has been followed by satisfactory results in some cases, according to the observations of Beard, Butler, Mussey, and Neftel. The question of accurate diagnosis of the cases reported as cured must still be considered as unsettled. The results apparently obtained should certainly awaken the profession to a trial of this method of treatment of a malady which internal medication, caustics, and the knife seem powerless to combat.

Bartholow reports a cure of four out of six cases of *fibroid tumors of the breast* by electrolysis. The remaining two patients failed to continue treatment for a sufficient length of time. He did not employ needles in any of these cases.

The *relief of hydrocele* by the introduction of two needles connected with the rheophores of a galvanic battery and brought within a half-inch of each other at their points has been reported by Rodolfi, Frank, Bartholow, and others. Some of the cases reported as cured required only one application.

In dismissing this subject it may be well to summarize the effects of electrolysis, as follows:

1. A feeble current tends to cause dilatation of the capillaries and the lymphatic vessels, and thus to aid in absorption.

2. A stronger current decomposes the salts and the water of tissues, and coagulates the albuminoid elements.

3. A disintegration of the tissues immediately adjacent to the pole which produces the effects previously described takes place, with an escape of bubbles of gas, when the decomposition of tissues is active.

4. As an eschar may be formed by a current of great intensity, it is maintained by some authors that the cicatrix which results from such a slough is soft and pliable if the eschar has been made by the anode, and dense, with a tendency to contract, when due to cathodal action. I am unable to confirm or deny this statement.

5. The danger in electrolysis is that of "doing too much" rather than too little. The former error can not be repaired; the latter can by repeated sittings.

6. When an escharotic effect is desired, it is well to have the needles made of zinc. The decomposition of the chloride salts forms indirectly the chloride of zinc, because the liberated chlorine attacks the needle. This is absorbed by the tissues adjacent to the needle, and an escharotic effect is thus produced. In the treatment of malignant growths such needles, with currents of weak intensity, and long sittings, seem particularly well adapted. This method is almost painless, and has produced excellent results in some cases reported.

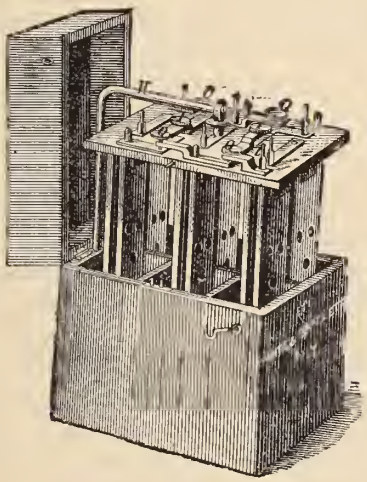
7. The introduction of needles into the tissues is not an absolute necessity when treatment by electrolysis is indicated. The same effects to a lesser degree may be obtained by placing the electrodes in contact with cutaneous or mucous surfaces.

8. The employment of iron needles has been suggested for the rapid coagulation of blood, on account of the styptic effect of the chloride of iron which tends to form by the liberation of chlorine from the chlorides of sodium, potassium, and calcium.

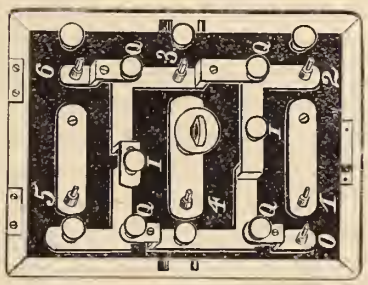
The Galvano-Cautery.—When a large quantity of elec-

tricity is forced through the resistance offered to its passage by a platinum wire or a strip of platinum (usually bent into the form of a knife), the heat produced causes the platinum to rapidly approach redness or whiteness. Such an arrangement is known as a "eautery-loop" or a "cautery-knife." The battery which is employed to generate electricity in sufficient quantity to accomplish such a result is known as a "eautery-battery." In cautery-batteries the plates are large and near together; henee unusual preeautions have to be taken to prevent "polarization," which takes place very rapidly on aecount of decomposition of the fluid in which the elements are immersed.

Of all the devices which have been suggested to overeome this difficulty, I prefer that of Dr. Piffard. In the battery devised by him the zine plates are perforated, so that the fluid can be forced through them upon the platinum plates by means of a rocking motion when the battery is in action. The assistant who operates the battery can produce any degree of heat required by making the plates move slowly or rapidly through the fluid. The key-board of the battery is so connected by means of large thumb-screws that the elements can be connected for either quantity or intensity, as the operator may desire. The rheophores are composed of large copper wire, heavily insulated with rubber.



(*a*)



(*b*)

Fig. 39.—Piffard's Cautery Battery. (*a*) The battery as suspended when not in action. (*b*) Arrangement of the top of this battery, showing the screws which regulate the connections between the different cells. The battery is rocked during its action to prevent extreme polarization. By making the movement slow or rapid, the heat of the loop or knife may be regulated at will.

I have made several improvements upon the original Piffard battery of late, which, in my opinion, will increase the ease of working the instrument. They are not, as yet fully perfected.

It may be advisable to again impress upon you the fact that batteries designed for ordinary medical purposes are totally unfit for heating a eautery-loop or producing an electric light. A battery designed for cautery purposes is also totally unfit for other purposes in medicine.

In operations upon the tongue, nose, pharynx, uterus, vagina, rectum, and in some other regions, the galvano-cautery seems destined to supersede the scalpel and écraseur. No blood need be lost in amputations of considerable magnitude, provided the operation is skillfully performed. If the loop is employed, it is slipped when cold over the part to be removed. It can be adjusted, therefore, with every precaution against accident. After the current is turned on, the heat of the wire even can be regulated with great precision. Care should be exercised against drawing the wire too closely to the handle, and in selecting a wire which will not burn off or prove too large for the battery employed. As in all surgical procedures, this instrument should be handled by an expert. It is well for a novice to practice upon pieces of meat or bone until he familiarizes himself with the details of its use, in case he meditates performing an operation upon a human subject. When operations are to be performed within the mucous cavities of the body, the patient has frequently to be trained to tolerate the necessary manipulation. A dull red heat is preferable to a white heat in dividing vascular tissues, and it is very important that the division be slowly performed. When the skin is to be embraced within the loop, it is well to divide it first with a eautery-knife, and subsequently to adjust the wire.

The eautery-knife has been successfully used in removing cancerous growths within mucous cavities, in tubal pregnancy, in tracheotomy, in extirpation of the breast, and many other similar procedures.

An attachment to the cautery-battery, known as the "dome cautery," consists of a coil of platinum wire over a cone of porcelain. These may be of any size, and the porcelain cone may be omitted if deemed necessary. It may be employed in destroying hypertrophied tonsils, hæmorrhoids, polypi, nævi, epithelioma, etc.

The great advantage which the galvano-cautery has over the use of the knife is the absence of hæmorrhage and of great pain. The platinum knife can be made of any form desired. There is no limit to special forms of attachments which may be devised to simplify its use in different regions of the body.

In operating upon the tongue, needles may be passed through the organ in front of the site selected for the loop, so as to prevent slipping of the wire. Bryant, who has had an extensive experience in this operation, recommends a twisted wire rather than a large one. There is some reason to believe that the heat tends, moreover, to destroy (in the case of cancerous growths) the germs of the disease which might elude the knife.

General Rules governing Electro-Therapeutics.

Before we pass to the consideration of special methods of employing electricity in the treatment of disease, it seems

to me advisable to suggest a few rules which may possibly aid you in deciding where and how to direct your treatment in any special case. There are, of course, some exceptions to each of these rules; but they are, nevertheless, sufficiently accurate to be used as guides in your practice:

1. Soak your electrodes in a weak solution of table-salt, not in simple water. This diminishes the resistance afforded by the skin at least fifty per cent.

2. Always press your electrode firmly and evenly against the part which it touches. This renders the current employed an even one to the patient and assists in its conduction.

3. Put a milliampère-meter or a galvanometer, as well as the body of your patient, into circuit, and record all your observations, respecting the current-strength employed, from its scale. It is neither scientific nor accurate to simply record the number of cells employed. Cells grow weak by long-continued use, by polarization, and other causes. In case a faradaic instrument is employed, a galvanometer is useless; hence you should record the number either of centimetres or inches of the primary or secondary coil employed.

4. Always endeavor to apply one of the poles to the part which is diseased. The plates which I show you indicate the situation of the "motor points" of the head, trunk, and extremities. Such plates will enable you to direct your treatment to any special nerve or muscle.

5. Acquire, by frequent experimentation upon yourself, a knowledge of the effects of different current-strengths, the situation of most of the more important nerve-trunks, the formulæ of contraction of healthy nerve and muscle, and all other information necessary to the use of electricity in medicine.

6. Never use too strong a current upon a patient at the first sitting. It may frighten him, and he may never return. It is always best to begin with weak currents; in the majority of cases weak currents are indicated rather than strong ones.

7. If you have no galvanometer, the intensity of a galvanic current can be approximately determined by the burning sensation produced in the skin by the electrodes when they are applied to it.

8. The "polar method" is more painful when the faradaic current is employed than when the galvanic current is used. It is not well to separate the poles of a faradaic machine too widely; pain is intensified, and no special benefit is gained by so doing. Remember that the faradaic current has no fixed polarity. A galvanometer will record the difference between the current produced by the "make" and "break" of the circuit only; hence it is of no value in determining the intensity of the faradaic current actually administered to a patient.

9. The "polar method" is absolutely requisite to electro-diagnosis when the galvanic reactions of nerve or muscle are being tested. It constitutes the best method also of administering the galvanic current for therapeutical purposes, because it is usually important that the anode or cathode exert its special influence upon the part diseased. The farther apart you place the poles, the less is the effect of the indifferent or neutral pole upon the part which you wish chiefly to influence.

Although clinical experience seems to prove that we obtain different results in the majority of cases by employing the anode or cathode upon the part to be influenced, I am inclined to question the correctness of the view that those effects are in any way dependent upon the direction of the transmitted current. We know that it is not possible to transmit an electric current in any one direction by means of animal tissues. Every current becomes diffused to a greater or less extent, as is illustrated in diagrams prepared by Erb and other authors upon electro-therapeutics. It is probably more correct to view the special effects obtained by employing the positive and negative poles of a galvanic battery as the effects of the poles themselves, rather than the result of the direction of the current.

10. Remember that the anode or positive pole of a galvanic battery is the sedative pole, and the cathode or negative pole is the stimulating or irritating pole. When the cathode is made the indifferent pole, it is well to use a very large electrode.

11. Do not change the polarity of a current during its application to a patient any oftener than circumstances demand. As a rule, it is unnecessary to do so at all. It causes unnecessary irritation, which should always be avoided. In the treatment of neuralgia, diseased conditions of the brain or spinal cord, and painful points, it should never be done without some special reason. It is positively contra-indicated when catalytic effects are desired.

12. When galvanic currents to the head are indicated (especially if the current is to be sent through the brain), employ only those of moderate intensity (save in exceptional cases), and do not reverse the current unless there is good reason for so doing. When you read about thirty-cell currents being sent through the brain, it is safe to suppose that the battery was not of the most active kind, or that the ability of the patient to endure such a current was very exceptional. It is rare to meet with a patient who can tolerate a current of more than from three to six milliampères through the brain, and it is not safe to break currents of high intensity when employed about the head.

13. Static electricity will sometimes produce muscular contractions when faradaic currents will not. In hysterical conditions, some of the spasmodic diseases, sciatica, and organic spinal affections, it is well to try this form of electricity when galvanism fails to afford relief.

14. Respecting the duration of individual applications of electricity in its various forms, my experience teaches me that short sittings accomplish as much, and often more, than long ones. I seldom exceed five or six minutes, unless I am endeavoring to induce catalytic action, to benefit chronic articular rheumatism, etc.; or when I am employing general faradization, general galvanization, central galvanization, electrolysis, the galvano-cautery, or other procedures which require a longer sitting. Frequently, thirty seconds to two minutes is all that is required when some particular part of the body is alone to be galvanized or faradized.

15. It is impossible to lay down any rule which will

guide you in determining the frequency of the applications required by any individual case. It is seldom necessary to employ this agent oftener than every day, and three sittings a week will suffice in the majority of cases. If the disease is of a chronic type, it is often advisable to occasionally discontinue treatment for a few weeks, and then to renew it with vigor. Experience has taught me that the effects of electricity are more vigorous after such intermissions. It is often well to change from galvanic to faradaic, and again to static, currents, from time to time, in the treatment of obstinate diseases which fail to progress satisfactorily.

16. I would advise you to be persistent in employing this agent when your judgment tells you that it is advisable to begin it. Many of the chronic forms of cerebral and spinal diseases are materially benefited and often completely cured by a proper course of electrical treatment which has been followed, with occasional intermissions, for some months during each year for several years.

17. As adjuncts to a course of electrical treatment, you will find massage, baths of various kinds, a change of climate, enforced rest in bed, and judicious internal medication, indicated in special cases. Delicate subjects, who suffer from neurasthenia, hysteria, persistent neuralgias, mental depression, sleeplessness, morbid fears, excessive "nervousness," rapid or extreme emaciation, profuse and persistent sweating of the palms or feet, dyspeptic symptoms, and the thousand other manifestations of debility, are especially benefited by these adjuncts to a judicious use of electricity.

18. When simple excitation of motor or sensory nerves is demanded, the faradaic or static current is the best one to employ.

19. As a counter-irritant, and in the treatment of anæsthesia, dry faradization with a wire brush excels all other electrical applications, unless it be the use of static electricity.

20. In spasmodic diseases, in neuralgia, and other like conditions, galvanism and static electricity are alone of material service.

21. Interrupted galvanic currents are of service when muscular contractions of a forcible character are desired. When degeneration of a nerve exists, these can not be produced by the faradaic current.

22. The size of the electrodes modifies the density of the current directly. When large, the current is less dense because it is more diffused. The cathode should, as a rule, be larger than the anode when electrical applications are being made.

Original Communications.

INTUBATION OF THE LARYNX.

By JOSEPH O'DWYER, M. D.

It was not my intention to publish anything in relation to my method of tubing the larynx in croup and kindred diseases until I had brought my instruments to a greater degree of perfection than I can claim for them at present, but, as several references to this subject have appeared in the journals and reports before medical societies, I have concluded to give the profession a brief account of the progress I have made, with a description of the instruments and the method of using them.

At the time I began my experiments, almost five years ago, and for more than a year subsequently, I was unaware of Bouchut's similar attempt and failure in 1858. His abandonment of any further experiments after such a limited trial as seven cases of croup, treated with very imperfect instruments, must be attributed solely to Trousseau's unqualified condemnation, in his report on this subject to the Paris Academy of Medicine, soon after the publication of Bouchut's cases. Trousseau was at that time strongly advocating the operation of tracheotomy, and, from the brief reports on this subject that I have read, it does not appear that he ever tried tubage of the glottis himself or witnessed its trial by others, but condemned it on purely theoretical grounds.

Bouchut in his experiments used a short cylindrical tube, introduced into the larynx on the end of a hollow sound, to which a thread was left attached and brought out through the mouth, for the purpose of removal. It is reported as having produced an extreme amount of irritation, in some cases necessitating its prompt withdrawal, but, notwithstanding the great lack of conformity between the shape of the tube and that of the rima glottidis, I am convinced from my own experiments that the greater part of this irritation was produced by the constant contact of the silken thread with the epiglottis and base of the tongue. Even in my earliest experiments, and with the imperfect tubes I was then using, I did not encounter any such marked irritation, but, on the contrary, was surprised at the tolerance displayed by the larynx for this kind of foreign body.

In attempting to construct a tube for the larynx, the first serious difficulty encountered was how to make it self-retaining. I could think of nothing more likely to accomplish this result than having it arranged in the form of a bivalve, similar to the bivalve speculum but elliptical in shape, with a narrow transverse diameter and having a shoulder to prevent its slipping into the trachea. This cannula was so constructed that, while being introduced, the blades were approximated and opened as soon as detached from the introducing instrument.

I will not enter into any details concerning my numerous experiments with various modifications of this instrument, except to state that it was always retained and gave prompt but transient relief to the dyspnœa, a return of which was due to intrusion of the swollen mucous membrane between the blades in the infraglottic division of the larynx.

My next trial was made with plain tubes, also elliptical in shape and about one inch long. The reason for having them so short was the belief that longer ones would be difficult to introduce. My first experience with these was in an infant aged two months and twenty-four days, in the suffocative stage of diphtheritic croup. Immediate relief to the dyspnœa, which was extreme, and a refreshing sleep,

followed the introduction of the tube. During the succeeding seventeen hours that it lived, most of which time was passed in sleep, almost a pint of milk was taken through a nursing-bottle. Death took place without any appearance of suffering.

The second case was that of a little girl aged three years and a half, in the service of Dr. J. Lewis Smith at the New York Foundling Asylum, suffering from the most urgent dyspnœa due to the same cause. In the presence of Dr. Smith and Dr. Blodget I introduced a tube with prompt and permanent relief. I removed it on the fourth day, but was obliged to reinsert it at the end of five hours, owing to a return of the obstruction. During an attack of coughing it was expelled on the seventh day, and, although the cough continued croupy for several days, with considerable dyspnœa at times, it was not found necessary to insert the tube again. She made a rapid recovery, with complete restoration of the voice. For the seven days this little patient retained the tube in her larynx she not only made known her wants in a very audible whisper, but kept up an almost continuous chatter with her attendants, the best possible proof that the irritation produced was not great. She swallowed fluids, such as milk, with considerable difficulty, usually coughing after each deglutition, but solids and semi-solids with comparative ease.

From the foregoing cases I was led to hope that these tubes would prove self-retaining without further modification, but in the next case, that of a boy aged four years, a tube of suitable size was expelled almost immediately; a larger followed the same course; the largest size I had, which was much too large for this age, was finally retained. Dyspnœa returned within twenty-four hours, and death took place with apparently as much suffering as if no tube had been used.

At the autopsy, the lower end of the cannula, which extended only into the narrow upper portion of the trachea where the latter unites with the infraglottic division of the larynx, was found obstructed by a thick deposit of pseudo-membrane, considerable of which also existed in the bronchi.

This case proved the necessity for longer tubes, and I procured a set, the largest of which was one inch and a half long, and the smaller somewhat shorter. As these were not retained any better than the former, and I was convinced that still longer ones could be introduced, I ordered a set the smallest of which was one inch and three quarters, and the largest three inches in length. They were constructed in accordance with a large number of measurements of the trachea at different ages, and would reach within half an inch or less of the bifurcation, thus overcoming obstruction in the trachea as well as the larynx. I also entertained the hope that the increased length would prove an important factor in preventing their expulsion, but had serious doubts about the possibility of introducing them. By having the curve on the introducing instrument very short, I experienced no more difficulty in passing these into the larynx than the much shorter ones previously used. In some cases they were retained, but in the majority were promptly coughed out.

The next attempt at overcoming this difficulty was the addition of a wedge-shaped piece of metal to the lateral aspect of the same tubes, half an inch from the upper extremity, with the thick end looking upward, which was intended to hold beneath the vocal cords. This accomplished the desired result, but at the same time retained them so firmly that their removal was rendered very difficult, and, as this would prove an insuperable objection, it was abandoned after a brief trial.

The tubes I am using at the present time differ in every respect, except length and caliber, from any heretofore tried. In order to give greater freedom of action to the epiglottis in protecting the aperture of the tube during the act of swallowing, I have given the upper extremities of these a slight posterior curve, with some degree of obliquity from before backward and upward, and, from my limited experience with them, deglutition is certainly less difficult than with the straight ones formerly used. But, as the epiglottis is only an accessory to the closure of the larynx, and the other more important factor, the action of its constrictor muscles, is prevented by the presence of the cannula, it is evident that the deglutition of fluids can never be perfect with any form of tube in the glottis.

The device adopted for preventing their expulsion consists in increasing the narrow transverse diameter about the center, without changing the caliber, so as to make the tube at this point almost cylindrical, and gradually inclining upward and downward somewhat in the shape of a double wedge. In the few cases in which I have used this modification it has proved self-retaining, and, should it continue to do so on a more extended trial, I believe there will be very little scope for further improvement, except, possibly, to increase the length so that it will reach still closer to the bifurcation, which would be of doubtful utility, as, after a very considerable experience in the dead-house, I have never yet found an exudation thick enough to produce obstruction in the lowest and widest portion of the trachea without at the same time having extensively invaded the bronchial tubes.

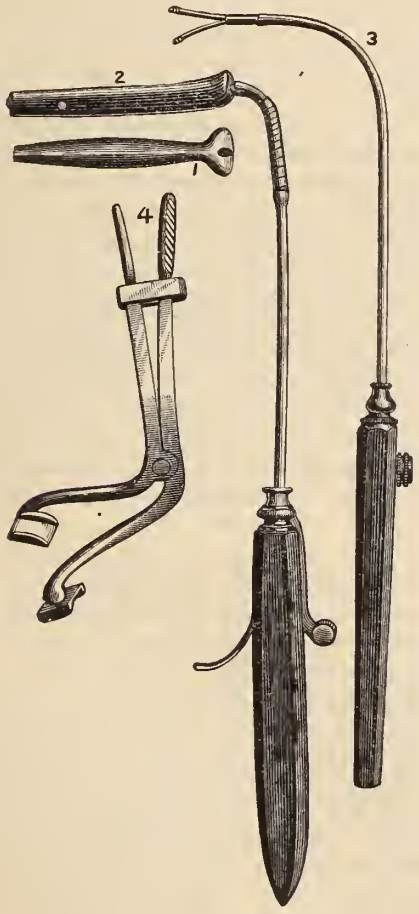
As all my work, up to a very recent period, has been of a purely experimental character, and as I am not prepared even now to say that further modification of these tubes may not be necessary in order to make them absolutely self-retaining, without which they would not be available for general use, I will leave all considerations as to the value of this method of treating croup and other acute stenoses of the larynx to be determined by a more extended trial in the future. At the same time I will venture the prediction that in the near future it will be recognized by the profession as a legitimate and valuable method of overcoming obstructions in the upper air-passages with a rapidity by no other means obtainable.

I believe these tubes will also prove valuable as dilators in chronic stenoses of the larynx or trachea, and particularly in those cases following tracheotomy where it is found impossible to dispense with the tube. Not having had any experience with such, I can give no facts as to the length of time a tube can be worn without injury; but some valuable inferences may be drawn from the time it has been retained

in acute stenosis. For instance, in two of my cases of diphtheritic croup that ended in recovery, the cannula was worn in each for the space of ten days without the slightest impairment of the vocal apparatus, and from this it is reasonable to infer that it would be tolerated in the healthy larynx for a much longer period, and probably, if worn intermittingly, for an indefinite period.

The following is the method of introducing the tube, which is done without the use of an anæsthetic: The child is held upright in the arms of a nurse and the gag inserted in the left angle of the mouth, well back between the teeth, and opened widely; an assistant holds the head, thrown somewhat backward, while the operator inserts the index-finger of the left hand to elevate the epiglottis and direct the tube into the larynx. The handle of the introducing instrument is held close to the patient's chest in the beginning of the operation, and rapidly elevated as the cannula approaches the glottis. As soon as the obturator is removed, and it is ascertained with certainty that the tube is in the larynx, the thread which is attached for the purpose of removal, should it be found to have passed into the œsophagus, is withdrawn, but at the same time the finger is kept in contact with the tube to prevent its being also withdrawn.

Its removal is accomplished in a similar manner; but, as it is difficult, on account of the struggling of the child, to



guide the extracting instrument into the narrow aperture of the tube, I prefer to give an anæsthetic for this purpose.

Fig. 1 gives an anterior view of the tube; Fig. 2, a lateral view of the same attached to the introducing instrument; Fig. 3 shows the extracting instrument; Fig. 4, the mouth gag.

Dr. J. Lewis Smith, in an article on croup, in the April number of the "American Journal of the Medical Sciences," speaks of tubage of the glottis in a manner that would lead his readers to infer that it was a well-recognized operation with which the profession was quite familiar. The only previous attempt ever made to tube the larynx (excluding the use of catheters and long tubes of every kind) with which I am acquainted was Bouchut's, previously referred to, the only result of which was to deter others from trying similar experiments. Dr. Smith's familiarity with this subject, no doubt, arose from our association at the New York Foundling Asylum, where my experiments were almost exclusively conducted.

There are several important points in connection with this subject the consideration of which I shall have to defer to some future time.

The manufacturer of these instruments is H. Keller, of 106 West Thirty-seventh Street.

ON CERTAIN
VASO-MOTOR DISTURBANCES
OF THE NASAL MEMBRANE.*

By WILLIAM C. GLASGOW, M. D.,
ST. LOUIS.

For a number of years my attention has been attracted by a series of cases which could not be explained by the well-known factors of inflammatory process. Resembling them in some particulars, still there are differences which necessitate an additional and independent influence for their production. The laws of vaso-motor action, although still imperfectly developed, would seem to explain them, and the success attending the use of therapeutic agents would seem to verify it. During the last few years the subject of vaso-motor disturbances of the nasal membrane has been very fully developed by several members of this society, and especially by Dr. Mackenzie, of Baltimore, Dr. Roe and Dr. Daly, and our co-laborer, Hack, of Freyburg. I find, however, that my experience of these cases has been somewhat different from that of my *confrères*, and I would aim in this paper to record my views and the conclusions which they would seem to justify. For a number of years my attention has been attracted by a series of cases characterized by great swelling, more especially of the cavernous tissue, a profuse discharge of limpid fluid, and abnormal paleness of the mucous membrane. Formerly, when they occurred during the summer months, I was content to consider them as modified types of so-called hay fever. When, however, I found they occurred during the year irrespective of seasons, I became convinced that there was a different agency from that then recognized as an essential factor in hay fever, *i. e.*, the pollen of Wyman, Blakley, and Phœbus. Dr. Beard's work first attracted my attention to the possibility of a neu-

* Read before the American Laryngological Association, June 24, 1885.

rosis being the chief factor in the disturbance, and gave me my first ideas of what I considered to be the true theory of these cases. Considering the so-called hay fever to be a functional disorder of the nervous system, in which the over-sensitiveness of the nasal mucous membrane occurs, and producing through this certain well-known reflex symptoms and disturbances of the normal vaso-motor action, I can still consider these cases as closely allied, both in ætiology and mechanism, with the so-called cases of hay fever. From a number of cases I have selected three, showing the distinct and different types of nasal disturbance. I would eliminate from consideration another class of cases in which we find neuralgia, especially orbital, supra-orbital, and frontal, occurring as a result of subacute rhinitis; although having many of the pathological conditions found in Case II, still there is wanting the primary neurotic element capable of producing the vaso-motor disturbance.

Case I.—I. W., an Englishman, a merchant, forty-five years of age, was brought to me for consultation by his physician. He was of stout build, somewhat florid, and had been generally healthy. He was suffering acutely with a neuralgia of the superior maxillary nerve of the left side, and complained of great obstruction, with a profuse flow of a clear watery fluid from the left nostril. He stated that this had only commenced with the neuralgia, and had been constant. On examination, the left nostril was found occluded by a swelling of the cavernous tissue; the mucous membrane was colorless in appearance, and seemed to be saturated with moisture which constantly oozed from its surface. The touch of the probe produced instantly an increase of the swelling and an increase of the discharge of the limpid fluid. The right nostril was normal and unobstructed. He was treated by his physician for the neuralgia, and received no local treatment. With the subsidence of the neuralgia the nasal disturbance disappeared.

Case II.—Mrs. P., thirty-two years of age, well developed, healthy, of a nervous temperament, and inclined to hysterical attacks. Has had three children; married eight years. Three years ago she noticed a nasal trouble for the first time, although for many years she had been suffering with follicular pharyngo-laryngitis and naso-pharyngitis. Her first attack occurred during pregnancy, and has been repeated at irregular intervals about four times a year. There is no special dependence upon atmospheric conditions. The attacks usually occur at the beginning or at the close of the menstrual epoch. The first symptom is a violent sneezing, occurring in paroxysms, with a profuse watery discharge from the right nostril. This is soon followed by an intensely painful spot in the right nostril, and by neuralgic pains radiating to the eye and the frontal regions. Congestion of the conjunctiva, lachrymation, and ptosis of the right lid soon follow. The right nostril becomes completely closed, especially toward evening, and there is generally accentuation of all the symptoms. The attack is accompanied by slight fever, with general lassitude and loss of appetite. There is also increase of the general arterial tension, as shown by the pulse, and pronounced accentuation of the second sounds of the heart. About the third day a plug begins to form in the nostril, which completely prevents the passage of air. The plug is of a dense structure. It is elastic and solid, and resembles no other nasal secretion that I have seen. It resembles somewhat a piece of rubber, and the elasticity is well marked on tearing it. The nostrils are now completely occluded by the swollen membrane and the plug, and the probe can only be passed by force. With the removal of the plug relief is given. The walls become less swollen and the nostril opens. During the next twelve hours another plug forms, and we find a renewal of the same symptoms, only in a moderated form. Without treatment this condition lasts ten days, with paroxysms varying in intensity and gradually diminishing toward the end. The nostril is then found in the normal condition, which is that of hypertrophic rhinitis. During the attack the mucous membrane is swollen and œdematous, pouring out quantities of limpid fluid. It is of a pale red, the pallor being in marked contrast to the color of the other nostril. It shows complete occlusion of the nostril, and it is exquisitely sensitive. The slightest contact of the probe causes increased swelling and profuse discharge, with violent paroxysms of sneezing; intense pain is felt radiating from the nose to the orbital and supra-orbital region, and immediate congestion of the conjunctiva is produced. Relief of this condition is most marked by bleeding the opposite nostril. The slightest touch of the knife produces a free hæmorrhage. The touch of the knife to the affected membrane increases the symptoms, and little blood is obtained unless the puncture is deep into the cavernous body. The blood is always pale and watery. The bleeding is then followed by the use of the hot alkaline sprays. By these means the swelling is reduced and the plug can then be blown out. I have also found the insufflation of the vapor of ether to have a very happy effect in promptly reducing the swelling and drying up the mucous membrane; the nitrite of amyl has also produced good effects.

Case III.—Miss S., thirty years of age, healthy, in excellent general condition. Has periodical attacks in the spring and fall of what she calls acute catarrh. When I saw her in March she complained of great obstruction of the nostril, and profuse watery discharge of both nostrils. On examination, both nostrils were found to be occluded by swelling of the cavernous bodies, the mucous membrane œdematous, of a pale color. A watery secretion seemed to be oozing from the mucous membrane and the discharge was profuse. The touch of the probe increased the swelling and the discharge, but produced no pain. A deep puncture in the cavernous body produced a slight hæmorrhage, the blood being very pale and watery. This always opens the nostril. Insufflation of the vapor of ether gave a certain amount of relief. The instillation of atropine into the nostril was also beneficial, as well as inhalations of camphor. These attacks would last about two weeks, and were always shortened by treatment, and the nostril would be left in a normal condition. In this case I found great benefit in the external use, in the shape of liniments, of the camphor chloral, aconite, and veratrine. This liniment was applied to the course of the fifth nerve and over the nose.

These three cases, although resembling each other in some respects, will be seen to be essentially different. In Case I we see the effect on the mucous membrane, the irritation being applied to the body of the nerve. In Case II we notice the effect produced by the irritant being within the nasal cavity in a case complicated by inflammation of the membrane. We find added to the original symptoms extreme sensitiveness and the tender spot with acute pain. The presence of the plug causes a swelling of the cavernous bodies, the swelling only subsiding on its removal. Case III is to me obscure. I have seen several such cases, some of them absolutely resisting all treatment for the reduction of the swelling. It may be due to some derangement of the vaso-motor centers, or some irritation within the nasal canal which has been overlooked. In the three cases, and in all of

this character which I have seen, there are found the three factors of great swelling of the cavernous bodies, abnormal paleness of the mucous membrane, and profuse discharge of the limpid fluid. And in all these cases these symptoms are aggravated by the application of an irritant to the affected membrane. These conditions I will consider to be due to disturbed nerve action, probably altered tone in the minute arterioles, produced by derangement of vaso-motor control. The mechanism which causes the swollen and œdematous tissue, the pale color of the membrane, and the profuse discharge must be explained simply on theoretical grounds; and, in the present state of our knowledge of vaso-motor action, it must certainly still remain problematical. Are the cavernous bodies congested, as has been asserted? Congestion presupposes a dilatation of the blood-vessels, with increased supply of normal blood. Under such conditions we shall find, not pallor, but increased redness. The prominent feature, however, in these cases is pronounced paleness, and this, in my opinion, disproves the possibility of dilatation of the blood-vessels. I would rather assume the opposite condition to exist—a contraction of the arterioles, due to an increased tone of the vessels caused by an augmented action of the vaso-constrictors. In short, the minute vessels supplying the arteries are in a state of spasm through nerve irritation, the general arterial tension is increased, the onward flow of the more solid portions of the blood is prevented, and the cavernous bodies of the mucous membrane become infiltrated with escaping white corpuscles and the liquor sanguinis. To these must be added the liquefaction and the increase of the glandular secretion, as the result of gland stimulation. The theory of spasm of the arterioles is supported by the favorable action of remedies which favor arterial dilatation—such as atropine and nitrite of amyl. In the present state of the knowledge of the laws of vaso-motor control it certainly is hazardous to base a theory on such laws. But the conditions existing in the nasal cavity seem to me to be explained solely by this means. I firmly believe that, whenever the laws governing the vaso-motor system shall be more thoroughly developed, we shall find more of the functional disturbances of the body to be due to disturbed vaso-motor action than is generally believed.

DISCUSSION.

Dr. Roe.—The subject of neurosis of the nasal membrane is certainly a very extensive one, and there are so many different factors which enter into the consideration of the subject, that many times the cause and effect are not properly differentiated. In many cases the nose is the objective cause, and in many cases, no doubt, the subjective cause. There is no reason why the nose may not be affected in a subjective manner, from irritations in other parts of the body, reflected through the sympathetic system, as well as the larynx or other portions of the body. But in the great majority of cases we find the nose to be the primary seat of the reflex irritations. As an illustration of this I will cite a case in point. Last summer, about a year ago, a gentleman came to me with a moderate naso-pharyngeal catarrh. In addition to his throat trouble he had marked pain in his chest, which caused him great anxiety. He suspected that he had a pulmonary difficulty. Careful examination of his chest revealed no trouble whatever. But in his nose there was, in addition to inflammatory trouble, an exostosis of the inferior turbinated bone, which came in contact with the septum. I advised him to have that removed, as the pain might be a reflected one, and as we are often surprised by the great amount of trouble which is reflected from the nose, and also as necessary in the cure of the nasal affection. He consented to the removal, after which, within an hour or two, the pain in his chest disappeared.

Dr. Robertson.—I have noticed in a large number of cases, in subjects of hay fever, this peculiar paleness of the mucous membrane. I think the case just related would naturally come under that subject—*i. e.*, that peculiar condition of the mucous membrane which is due to an irritation of the nervous system. I have such a case in mind who, I consider, had chronic hay fever. She would have paroxysms of sneezing and discharge of watery fluid from the nose. The peculiar paleness of the mucous membrane and the usual hyperæsthesia of the membrane were very marked. The attacks were frequent. They came on during the summer, fall, or winter, but were undoubtedly of nervous origin, because, with any mental disturbance, from going to a party, or to school, she would sneeze twenty or thirty times, and then the watery discharges would take place. This case was treated with spray and with a preparation of eucalyptol, with relief for a few days. I have noticed a number of cases of hay fever in which this condition of the pallidity of the mucous membrane and these peculiar watery secretions were very marked. As far as swelling of the membrane is concerned, it frequently occurs during the early stages of the disease, but gradually subsides. I believe it due to a swelling of the cavernous portions of the turbinated bodies, with contraction of the membrane itself. There might be contraction of the arterioles and capillary blood-vessels of the skin, and still directly underneath the skin, congestion. In the turbinated bodies this would only occur in conditions of disturbance of the vaso-motor system.

Dr. Mackenzie.—I do not propose to reiterate on this occasion all that I have said and written on the subject of which Dr. Glasgow treats; but there is one point in regard to the pallor of the mucous membrane, which is a good one, to which my attention has not been directed before. On the contrary, I have found in my experience that the opposite condition is the most prevalent one. I think with the cases which Dr. Glasgow has described you will allow me to include a number of so-called hay fever, and of these some to which I have ventured to give the name of sympathetic rhinitis. In its pathology two factors enter. The peculiar irritability of the tissue of the nose may be due to different causes: either from some local pathological process, or from a host of other peripheral influences, or from some irritation starting in the nervous centers, or possibly due to some disease of the nervous system as a whole, or from some reflex irritation from its various parts, or, finally, from some disease of a distant organ. In one of my papers on vaso-motor coryza I have called attention to the purely psychical element in the production of the paroxysms. Lately I saw a lady who had been suffering for over fifteen years with certain forms of so-called hay fever. The paroxysms were so violent that she was compelled to take to her bed and remain there in great suffering until it was over. It was unquestionably a case of so-called rose cold. She could not go into a room where roses were without bringing on an attack. She was nervous in the ordinary acceptation of that term, but was not, however, hysterical. I had a perfect artificial rose constructed, of such exquisite workmanship that it was the exact counterpart of the original. I carefully kept this in a clean place in my office behind a screen, and when she was expected I carefully removed every particle of dust from it by a thorough washing. Several days before I had used the galvano-cautery, and when she came

to my office that morning she said she had never suffered so little during the past fifteen years as during the three days prior to coming to my office. After she had been in my office over a quarter of an hour I produced the artificial rose, and, sitting down in front of her, dangled it in my hand, at the same time conversing on some topic foreign to her case. In less than a minute she said she would sneeze. In less than two minutes she had intense itching at the nose, and in less than four minutes from the time I produced the rose from behind the screen the symptoms of asthma had commenced. As soon as the difficulty in breathing had commenced, I removed the rose and told her it was an artificial rose, and her astonishment was of course very great. Four days afterward she came to my office. I produced the most perfect specimen of a real rose, into the center of which I plunged her nose and kept it there a long time. I tried to get all the pollen I could in her nasal chambers, and I think I was fairly successful. I kept it there for about five minutes without exciting the slightest tendency to the so-called rose cold. On the day on which I performed the experiment with the artificial rose she entered my office apparently a well woman, and left it with one of the severest coryzas she ever had. The pallor of the mucous membrane is a point of extreme interest, and worthy of our future consideration.

Dr. Harrison Allen.—I saw a case last winter which illustrated the point taken by Dr. Glasgow. A lady, the subject of Bright's disease, suffered from intense irritation of the nasal chambers, accompanied with absolute occlusion. The condition was undoubtedly due to a constitutional cause, and yielded to general remedies.

Dr. Rice.—I have been pleased with Dr. Glasgow's classification of these cases, for there certainly is great difference in the pathological appearances presented. In some we find all the color of inflammation, and in others the pallor which has been mentioned. In hay fever the inflammatory condition enters more largely than in these so-called "neurotic cases" which Dr. Glasgow has spoken of, the redness and swelling in one case being due to dilatation of the arterioles, while the white, boggy enlargement is caused by the transudation of serum, the capillaries being contracted. I have noticed the different action of cocaine upon these two classes, and it may be made a means of differential diagnosis. In simple inflammatory hypertrophies of the nose we know that the swelling is instantly and completely reduced when cocaine is applied; but in the white swellings little effect is produced in causing absorption of serum.

Dr. Glasgow.—I think the point that the irritation of the cavernous tissue is the primary one is not valid. The swelling is simply the effect, and due to irritation. In the first case I reported we had a beautiful illustration of disturbance without an inflammatory condition. There was profound pallor, such as I have never seen, except in the cadaver. Now, here irritation was increased, and the swelling of the cavernous tissue was simply the effect of this disturbed nerve action. In the second case there was a swelling of the cavernous tissue, due to this same cause. Call it vaso-motor or not, it is a disturbed action due to irritation in the nostril. Remove the plug, and you immediately remove the swelling; so that the swelling could not have been primary, but a secondary effect of the primary nerve irritation. Dr. Mackenzie also beautifully illustrates this fact in his rose experiment. I am a profound believer in this mental influence; but I neglected to mention in my case that the lady could intensify her colds by thinking about them. If she had any little annoyance during the day, toward evening her trouble would be greatly intensified.

The University of Vermont.—Dr. L. M. Bingham, of Burlington, has been appointed Professor of Surgery, succeeding the late Dr. J. L. Little.

TWO CASES OF UNILATERAL TEMPORAL HEMIANOPSIA.*

By CHARLES STEDMAN BULL, M. D.,

LECTURER ON OPHTHALMOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

Case I.—*Unilateral Temporal Hemianopsia, with Central Scotoma of the Other Eye.*—Colonel A. D. N., aged sixty-six, a retired officer of the army, was first seen by me on June 28, 1884, and told the following history: In the summer of 1849, while at one of the Government posts on our western frontier, he was struck by lightning as he was standing at the door of his tent. He fell to the ground and remained unconscious for several hours. When he regained his senses, he discovered that he was blind in both eyes; but this condition rapidly improved, so that at the end of a few days he had regained his sight, and in a short space of time had the perfect possession of all his faculties. He remained perfectly well in every respect till 1857, nearly eight years later, when the muscles of the left thigh and leg began to atrophy, and almost simultaneously there appeared a sudden temporal hemianopsia of the right eye. The paresis and atrophy of the muscles of the left lower extremity slowly but steadily progressed till 1859, since which time there has been no change. There has been no change in the field or power of vision in the right eye since the hemianopsia first appeared. He walks with comparative ease, but the muscles of the left leg are markedly smaller than those of the opposite side, and he tires easily on walking. About six months before I saw him he noticed a central obscuration of vision of the left eye, which came on suddenly, and this scotoma has existed ever since, and he thinks has grown larger. He has never had rheumatism or syphilis, has no hypertrophy or valvular disease of the heart, and repeated and very careful examination of the urine has not been able to determine any signs of chronic degenerative nephritis. He has had intermittent fever of the congestive type several times severely, and during the past six months he has had several attacks of fainting, which have occurred without any warning. He has never been addicted to drinking, and for many years has not touched alcohol, but he has all his life chewed and smoked tobacco to excess. He was a man of fine physique, with snow-white hair, but with a rather feeble, cautious gait. On testing the vision, it was found in the right eye $= \frac{15}{30}+$, with no vision on the temporal side of the median vertical plane of the eye. In the L. E., $V = \frac{6}{10}$ eccentrically. A very careful examination of the field of vision was then made, and repeated at each subsequent visit, but all the examinations gave the same result. In the R. E. there was entire loss of the temporal half of the field. In the L. E. there was concentric narrowing of the field and also a central scotoma, which was of an irregular oval in shape, with the long diameter of about 30° vertical, and the short diameter 20° horizontal. An ophthalmoscopic examination showed that the media were perfectly transparent, and oblique illumination proved that the iris was normal in color and reaction. Both optic discs were of a dirty grayish-white, and in the left eye the outline of the papilla was ill-defined and at places swollen, as is met with after a neuritis. In both discs there was a deep, overhung, almost glaucomatous excavation, with pulsating veins, but no pulsation in the arteries. In the L. E., in the region of the macula, was a large, irregular retinal hæmorrhage, of the apparent size of two or three papillæ, with its long diameter vertical and of a different tint in different portions, showing that there had been several extravasations at different dates. The center was evidently the

* Read before the American Ophthalmological Society, July 15, 1885.

oldest in date, and the blood had been partially absorbed, giving here and there a glimpse of white sclera showing through an atrophied choroid. The rest of the fundus in both eyes varied but little from the normal in its appearance. The tests for color-blindness showed that in the L. E. the color-sense was defective for all but blue, while in the nasal half of the field of the R. E. it was normal though sluggish. The tension was normal in both eyes, Fig 1.

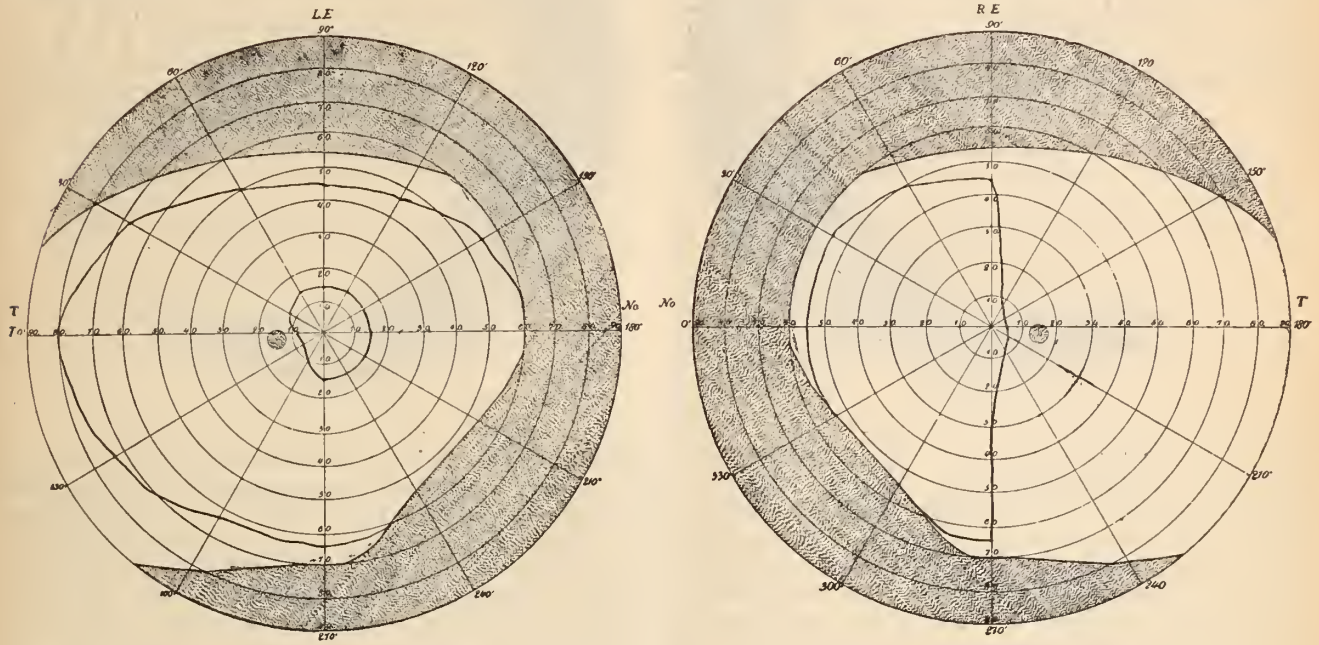


Fig. 1.

Between June 28, 1884, and March 24, 1885, I saw the patient at intervals of three or four weeks, but never discovered any change in the condition of the eyes. On the latter date he complained of seeing what he called a "ball of fire" at times in front of the L. E., of transient duration, which was always followed by a spiral or corkscrew appearance of light, which lasted some seconds. In testing his vision in L. E. at this date, I found that it had risen to $\frac{15}{40}$ eccentrically in the nasal half of the field, but there was no change in the ophthalmoscopic appearances, except a gradual absorption of the extravasated blood in the region of the macula, and no recurrence of the hæmorrhage.

Case II.—*Unilateral Irregular Hemianopsia, with Concentric Limitation of the Field of Vision of the Same Eye.*—Mr. D. W., aged sixty, was first seen by me on March 27, 1885, and gave the following history: On Christmas-day, 1884, while standing on a street-crossing, he was knocked down and trampled upon by a horse. When picked up he was unconscious, and there was a large laceration of the scalp covering the frontal bone above the left eye. He was carried in an ambulance to his home, and, in the transit, regained his consciousness, so that on arrival at his residence he got out with assistance and walked up-stairs to his bedroom. He then again became unconscious, and remained either semi-comatose or delirious for

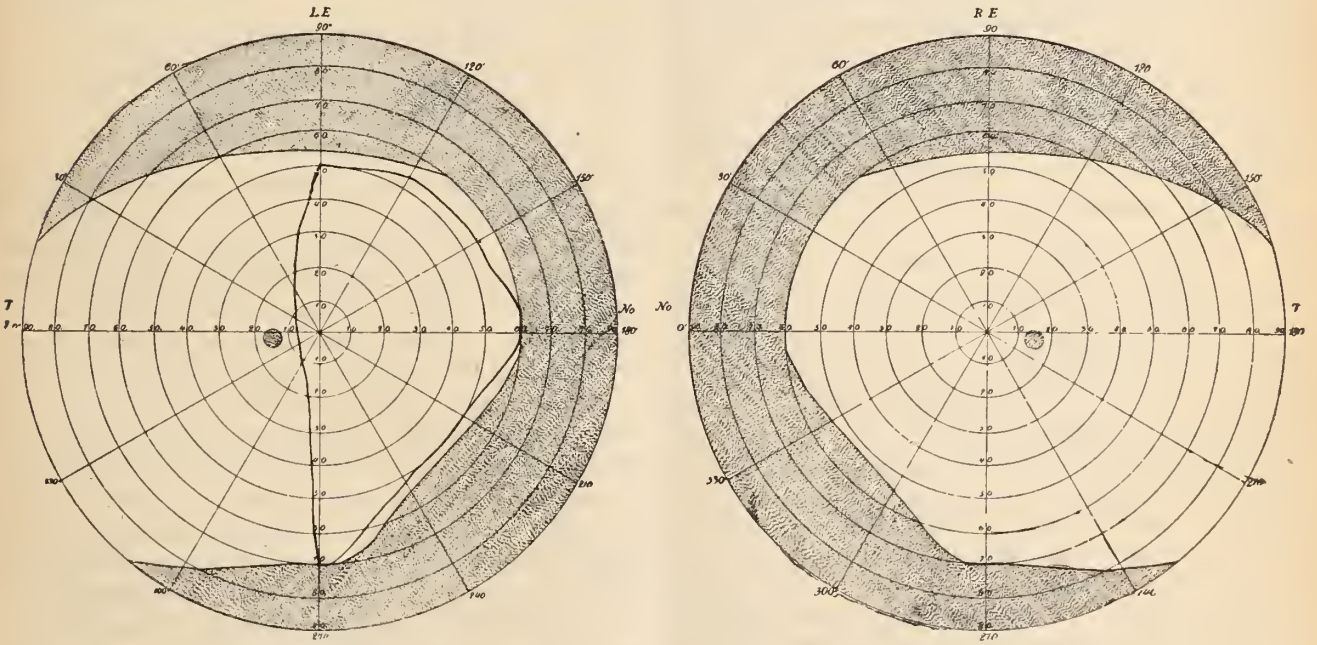

Fig. 2.

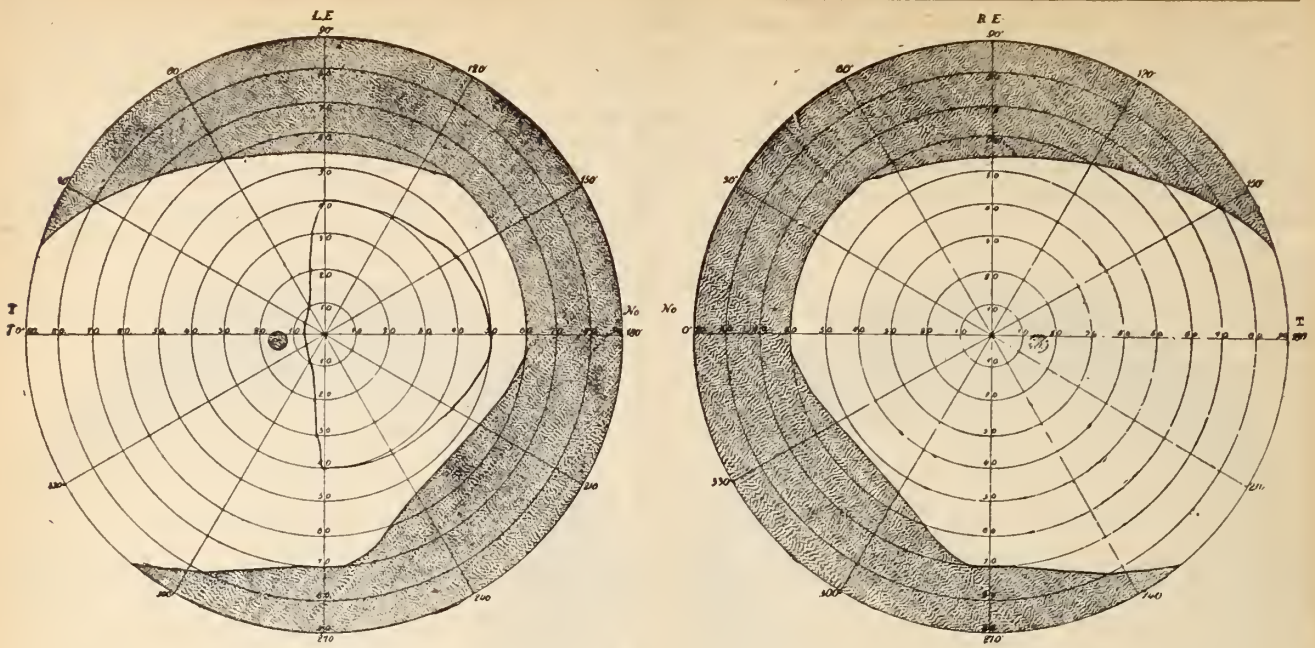

Fig. 3.

four weeks. There were also two ribs on the right side fractured at the time of the accident. An examination of the scalp-wound, which was of an irregular shape and about three inches long, showed that it ran from above, close to the hairy scalp, downward and inward toward the median line of the left eyebrow. Beneath this laceration was a depressed fracture of the skull of some considerable extent. The patient was not trephined, but was treated mainly on the expectant plan. Erysipelas of the scalp developed within the first week, beginning at the wound and extending all over the face and scalp. Both eyes were closed by the swelling of the eyelids, and this lasted for several weeks. When he regained complete consciousness, and the swelling of the eyelids had disappeared, he noticed that he could not see anything on his left side if the right eye were closed, and this condition remained unchanged till I saw him. In addition to the left temporal hemianopsia, he complained that, whenever he attempted to write, everything swam before him, but said that he could read with ease for any length of time without fatigue. He had always been hypermetropic, but had never worn glasses for distant vision. An examination showed $V = \frac{15}{70}+$ in *both eyes*, and with Sph. + D 2 $= \frac{15}{15}+$. He also read Sn. D = 0·25 at 10″ with Sph. + D 4. An examination of the field of vision showed that it was perfectly normal in the R. E.; but in the left eye there was a well-marked, though somewhat irregular, temporal hemianopsia. The color perception was normal in the R. E., and normal in the perfect half of the field in the L. E. An ophthalmoscopic examination showed on the right side a normal hypermetropic eye, with clear media; but in the L. E. the opic disc was white, with clearly defined outlines, and the arteries were reduced in caliber. The tension was normal in both eyes. There was no tenderness on pressure over the seat of the fracture in the frontal bone, nor along the course of the supra-orbital nerve. On the contrary, the patient complained of a numbness along the course and distribution both of the supra-orbital and infra-orbital nerves ever since he became conscious of his own sensations. This patient was seen by me, at intervals of a few days, from March 27th to date, and there has been no change in any of the conditions, except a gradually increasing concentric limitation of the nasal half of the field of the left eye. His last visit was made on June 22d, at which time a careful examination was again made of the field, and his vision also tested. Figs. 2 and 3 show the condition of the field of the left eye at the date of his first visit, March 27th, and of his last visit, June 22d; the latter also shows the gradual concentric narrowing of the nasal half of the field. A possible explanation of the visual defect in this case may lie in an extension of the line of fracture from the frontal bone through the roof of the orbit, backward to the optic foramen, and a consequent injury to the fibers of the optic nerve, which are distributed to the nasal half of the retina. There seems to be but little doubt that the amblyopia is progressive, and that the pseudo-hemianopsia will end in complete amaurosis of one eye.

THE EFFECT OF COCAINE UPON THE HEALING OF WOUNDS.

By LUCIEN HOWE, M.D.,
BUFFALO.

The anæsthetic effect of cocaine upon the eye, already so well known, suggests an inquiry as to the influence it may also have on the healing of wounds. A considerable time must necessarily elapse before clinical experience can furnish sufficient data to warrant conclusions which are entirely reliable. Different individuals and the circumstances accompanying the operations vary so greatly that, in spite of the many cases already published in which cocaine has been used, only a series of those exactly similar would furnish an average for just comparison. In certain rather rare instances, it is true, the same operation is made on each eye of the same individual at the same time, and in these the effect of the drug can be tested. But such cases are by no means numerous. I have, therefore, endeavored to determine its influence upon the healing of wounds by producing equal lesions in both eyes of an animal, and then comparing the one treated with cocaine with the other, either left to itself or treated with atropine. The principal objects of this inquiry were to detect any unfavorable influence cocaine might exert upon such wounds by reason of the irri

tation produced, or of the effect upon the nerve supply. On the contrary, if its action was advantageous, it was important to determine what parts of the eye it affected, and if for the iris or any other portion it was as reliable as atropine. It is well to settle such questions as soon as possible after the discovery of an agent like this, whose anæsthetic properties naturally excite unguarded enthusiasm or too great confidence in a really valuable drug. Accordingly, in October last, in the laboratory of Professor Zuntz, in Berlin, I noted the healing process in wounds as follows:

Rupture of conjunctiva in one rabbit.
Rupture of conjunctiva in two Guinea-pigs.
Abrasion of corneal epithelium in two rabbits.
Abrasion of corneal epithelium in one Guinea-pig.
Abrasion of corneal epithelium in one cat.
Burn of conjunctiva and cornea in two rabbits.
Puncture of cornea in one cat.
Iridectomy, simple, in one rabbit.
Iridectomy, iris being left in wound, in two rabbits.
Iridectomy, iris left in wound, in three Guinea-pigs.
Traumatic cataract in three Guinea-pigs.

It would be unnecessary repetition to rehearse in detail the healing of each of these wounds, yet a few examples are not out of place illustrating not only the process of repair in general, but also the form of record kept in these cases. In these, the eye treated with cocaine is indicated by "C."; the other by "L." or "R.," as it happened to be left or right. For convenience, the amount of secretion in the conjunctiva, or the extent of swelling there or elsewhere, is indicated in degree—1 representing the minimum and 3 the maximum.

Guinea-pig.—Extensive tear in conjunctiva, reaching from outer to inner canthus.

Comparison of Cocaine with Atropine in the Healing of a Burn with Lime, involving Conjunctiva and Cornea of a Rabbit.—A sufficient amount of unslaked lime was placed on the upper half of the conjunctiva and cornea to produce an eschar on all the palpebral and ocular portions of the former, and also to whiten the latter over a space measuring five by six millimetres. Exactly the same was repeated in the other eye, and both were thoroughly washed with distilled water, to remove all remaining particles of lime. A two-per-cent. solution of cocaine was then dropped into the right, and one of atropine, of the same strength, into the left.

Large Brown Rabbit.—A linear wound at the corneo-scleral margin, six millimetres long, was made in the left, and the prolapsing iris allowed to remain. Exactly the same operation was made on the right. A piece of cotton was placed on each eye, that of the left being saturated with a two-per-cent. solution of cocaine, and that on the right with water only. In order that both might be kept moist, they were then covered with thin India-rubber, and the animal placed with his head resting easily, but firmly, so that the covering could not be scratched off.

No attempt has been made in any systematic manner to verify these experiments by a similar series upon the human subject. One is not justified in subjecting an eye recently operated upon for iridectomy, for example, to the manipulation, or even violence, which such an exact examination often demands, but the great majority of clinical experience thus far seems to be in perfect accord with the results reached by experiments upon the animals mentioned.

These conclusions may be briefly stated as follows:

1. In lesions of the conjunctiva, perfect solutions of the hydrochlorate of cocaine have no appreciable effect, beneficial or otherwise, upon the healing process. When the solution is imperfect, a slight additional hyperæmia is produced, which persists longer than in the other eye, but this is ordinarily of no practical importance.

2. In lesions of the cornea it has a beneficial effect, like other mydriatics, but inferior to that of atropine. In imperfect solutions a perceptible abrasion of the epithelium is produced, and, though this is quickly renewed, the healing is thereby delayed by the cocaine.

3. In wounds of the iris the mydriatic action of cocaine is evident; but here again it is inferior to atropine, and is of little value in detaching firm synechiæ. Imperfect solutions, however, do not appear to hinder the healing process any more than when applied to the conjunctiva or cornea. Indeed, as strong mixtures possess decided antiseptic properties, they would seem to exert a favorable effect in this respect.

The Death of Prof. von Fehling, of Stuttgart, is announced in our European contemporaries. He was widely known as the originator of a ready method of testing for grape sugar in the urine by the use of what is everywhere known now as "Fehling's solution."

SYRUP OF HYDRIODIC ACID IN ACUTE INFLAMMATORY RHEUMATISM.

By JAMES CRAIG, M. D.,
JERSEY CITY, N. J.

In an article appearing in the New York "Medical Record," April 21, 1883, I speak of the manner in which I was led to the use of this syrup in cases of acute inflammatory rheumatism. The object of the present article is not merely to reiterate what was said in that publication, but to emphasize my entire faith in the efficacy of this treatment by the citation of cases of cure, and the statement that I have yet to find a case in which, the syrup being properly used, it has failed to meet my expectations.

Since the publication of my first article this method of treatment has been employed by a number of physicians with success, shortening the duration of the disease, relieving pain, reducing temperature, and in all cases leaving the patient without heart complications, the remedy preventing exudation and organization of plastic material. I order the syrup in from two- to three-teaspoonful doses, in a wine-glass of water, every two hours, lessening the dose as improvement takes place, and continuing the syrup for about a week or ten days after symptoms have disappeared, to insure recovery and prevent relapse.

The old method of treatment by the use of bicarbonate of potassium is slow, and its continued use brings about a depraved condition of the system by reducing the amount of fibrin in the blood and destroying the red corpuscles. It also acts as an irritant to the stomach, injuring the mucous membrane and causing loss of appetite. The depraved condition of the blood can be seen in the pale face, pallor of the lips, and enfeebled action of the heart, requiring weeks for the patient to recover from the disease and its treatment. Salicylic acid has had its day and has been found wanting, being replaced by some with oil of gaultheria—salicylic acid in another form.

This acid, from its difficult solubility, allows its crystals to irritate the throat and stomach, and, in some, occasions so much vomiting as to render its continued use impossible.

Syrup of hydriodic acid is a good remedy in sub-acute rheumatism also, but is not so prompt in its action as in cases of the acute form.

I have tried it in chronic rheumatism, but can not say that I have observed any good results. In some cases I use a lotion as follows:

℞ Liq. plumbi subacetatis..... ℥ ij;
Tincturæ arnicæ..... ℥ ij;
Aquæ puræ..... ℥ iv.

M. Sig. Add one part of the solution to three parts of hot water, and apply saturated flannels to the inflamed joints. It usually gives immediate relief. This solution is of a beautiful yellow color when properly prepared.*

* The tincture of arnica should be made according to the United States Pharmacopœia, and not by using the fluid extract of arnica flowers, and making a tincture by the addition of diluted alcohol, as this tincture makes an unsightly dirty-brown mixture.

The following are a few of the numerous cases of successful treatment of acute inflammatory rheumatism by the use of the syrup of hydriodic acid:

Case I.—On December 16, 1880, I was called to see Mary S., aged eight years, who was suffering from a very severe attack of acute rheumatism. The knees and ankles were very much swollen, and the pain was so excruciating that she could not bear the weight of a sheet to touch her legs. Protected them with a barrel-hoop cut in two and crossed. Prescribed syrup of hydriodic acid, in teaspoonful doses, every two hours. The pain was subdued within fifteen hours. Continued treatment for about a week. No relapse.

Case II.—Mrs. E. P. R., aged thirty-five years, was seized with a chill on January 9, 1883. Began the use of the syrup of hydriodic acid on the 10th, and continued the treatment, in three-teaspoonful doses, diluted with water, until the 16th, when the patient was dismissed cured.

Case III.—Mrs. C. F. C., aged thirty-nine. I was sent for on March 21, 1883, and found her suffering from acute rheumatism; prescribed the syrup in two-teaspoonful doses: continued treatment to the 29th, when I made my last visit, and found my patient dressed, sitting up, and free from pain.

Case IV.—B. E., aged fifty-five, a merchant, has had rheumatism for many years. I attended him with a subacute attack on the 13th of January, 1884; left him on the 18th free of pain. The medicine was given in tablespoonful doses, every two hours, up to this time, when he was ordered to continue its use in smaller doses and at longer intervals for another week. On the 4th of April, 1885, I was called to attend him with a similar attack. Used the syrup. The pain was still severe on the 5th, so I used the lotion to his hand and knee, which gave immediate relief. The last visit was made on the 8th, at which time he was entirely free of pain and swelling.

Case V.—Mrs. L. A., aged twenty-seven, was taken with a chill, followed with high fever, on the 21st of January, 1885. I was called on the 22d, and found her suffering with an attack of acute rheumatism, affecting both upper and lower extremities. As usual in such cases, prescribed the syrup in three-teaspoonful doses, every two hours, using the lotion as well. She was relieved in thirty-six hours, and was about the house in one week. Ten days after I made my last visit. Her husband told me that she had had a relapse from imprudently sitting by an open window. Medicine was repeated, and in four or five days she was again free from pain.

Case VI.—W. C., aged twelve years, of stout build, was seized with rheumatism in knee, ankle, and hand. Saw him for the first visit on February 20, 1885. I prescribed the syrup in two-teaspoonful doses, diluted in water (which should always be done); the lotion was also used in this case. My last visit was made on the 28th, when I left him walking about the house.

Case VII.—S. G. S., aged thirty-eight, clerk, was seized on the morning of the 15th of March, 1885. Commenced the use of the syrup on the evening of the same day; he was free of pain and swelling on the 16th, and went to his business on the 17th. He has had no return.

Case VIII.—J. C., aged fifty-one, has had chronic rheumatism for more than twenty years. About the beginning of March, 1885, he was seized with a violent pain in right knee while walking, followed, after a few days, with heat and swelling. The affected knee was two inches larger in circumference than the other; the trouble was looked upon as a sprain for about three weeks, when rheumatism was suspected. Began the use of the syrup in tablespoonful doses in a gill of water; he felt relief after the second dose; treatment was continued

every two or three hours until eight ounces of the syrup were taken, which removed all further trouble. No relapse.

Case IX.—John L., aged forty, coachman, was taken down on May 4, 1885; his knees were very much swollen and very painful. He was given the syrup in tablespoonful doses every two hours, and was able to be around the house in four days and a half. He had a relapse on the 24th of the same month, caused by exposure, and was seized with a chill, and again used the syrup and lotion. Advised the syrup to be continued in decreasing doses and at longer intervals for a week or ten days.

Case X.—J. F., aged forty, conductor. I was sent for on May 29, 1885, and found his right knee and left ankle swollen and very painful. He also complained of pain in his fingers and toes. The syrup was given, in tablespoonful doses, every two hours; the lotion was also used. He was free from pain within forty-eight hours. Dismissed him on the 3d of June without pain or ache.

The following cases were kindly furnished me by my friend, Dr. Conrad Wienges, of this city:

Case I.—*August 28, 1883.*—P. M., engineer, aged forty-nine; subacute rheumatism in both knees and ankles. Gave him two teaspoonfuls of syrup of hydriodic acid every three hours. Dismissed him September 30th, free from pain or ache. This patient had several attacks previous to this one, but was always confined to the house from four to six weeks.

Case II.—*June 16, 1884.*—Mrs. L., aged thirty-five; subacute rheumatism in the chest and right shoulder. Two teaspoonfuls of syrup of hydriodic acid every four hours. It relieved the pain entirely in twenty-four hours.

Case III.—*March 30, 1885.*—F. McC., nineteen years old; worker in tobacco factory; acute rheumatism in both knees and ankles. He was ordered two teaspoonfuls of syrup of hydriodic acid, every two hours, in a wineglass of water. At my next visit, on the 31st, he could flex his knees and move the foot with comparative ease.

April 1st.—The swelling had vanished and the patient was sitting up when I called. He was dismissed on the 3d, cured, and resumed his occupation on the 3d of April.

Case IV.—*May 7, 1885.*—G. E. P., thirty years old; deck-hand; acute rheumatism affecting his right shoulder and elbow. The pain was excruciating—so much so that one fourth of a grain of morphine, every hour for four hours, was given to produce immediate relief. He took two-teaspoonful doses of hydriodic acid every two hours. At my next visit, sixteen hours later, the pain had almost disappeared, and he could move the arm with ease in any direction. On the 9th he was entirely free from pain, and was dismissed, cured, on the 11th.

The following cases were kindly furnished me by Dr. Baumann, House Physician at the New Haven Hospital, New Haven, Conn.:

Case I.—M. F. M., Irish, aged twenty-five; single; painter. Was attacked April 24, 1885, with acute rheumatism in the ankles and knees, and on the 25th it extended to his shoulders, elbows, and wrists. Entered hospital this day; temperature 103° F. The pain was so severe that the slightest movement caused great distress. No cardiac lesions. Ordered syrup of hydriodic acid, one teaspoonful, every two hours.

28th.—Patient has improved greatly. Temperature 100°; joints not so painful.

29th.—Improvement continues. Patient got up to-day.

May 4th.—He is up and around the wards, and has no pain in his joints. Treatment continued.

5th.—Discharged cured.

Case II.—P. M., aged twenty-two years; has been under treatment in the surgical wards since April 28th for gluteal abscess. He had an attack of rheumatism in both wrists and hands, and pain in the chest and back. The pain and swelling were so severe that he could not bear to be touched. Temperature 100°. Ordered salicin, grains xx, every three hours, and sodii bicarb., 3 ss., every three hours.

May 30th.—No marked improvement, and was transferred to medical wards. Salicin was stopped and he was given syrup of hydriodic acid, two teaspoonfuls every two hours. Temperature 101·6°. Morphine, hypodermically, had to be administered during the night on account of severe pain.

31st.—Pain diminished; morphine not required. Temperature 101·2°.

June 1st.—Patient slept well without the use of anodynes. Fingers could be moved without pain, but the chest was still painful.

2d.—Patient comfortable; all pain and inflammation have disappeared. He fed himself for the first time to-day. Temperature 100°.

5th.—He was transferred to a surgical ward, and syrup stopped.

8th.—Temperature rose to 100·3°, and another attack threatened. He was given the syrup in the same doses. Next day temperature fell to normal. The syrup was continued a week, and then gradually diminished and stopped.

Remarks.—The patient had previously had several attacks of rheumatism, each lasting from two to four weeks. He had a mitral regurgitant murmur on admission.

The syrup was tried in a number of subacute cases with good results, but was unsuccessful in chronic cases.

I hope that I have thus been able to impress upon the minds of my readers the fact that, by the use of the syrup of hydriodic acid in cases of acute inflammatory rheumatism, our results will be far more satisfactory, and our cases less tedious and uncertain.

LETTER FROM WASHINGTON.

The Wales Court-Martial.—Laparotomy for Gunshot Injury.—Last Year's Outbreak of Cholera in France.

Washington, *July 31, 1885.*

The findings of the naval court-martial before which ex-Surgeon General Wales was recently tried were made public to-day. The court sentences him to suspension from rank and duty for five years on furlough pay, and to retain his present number in his grade during that period. The Secretary of the

Navy says: "In expressing its approval of the proceedings, findings, and sentence in this case, the department deems it proper to remark that no dishonest or corrupt act or motive involving any breach of personal integrity on the part of Medical Director Philip S. Wales, as chief of the Bureau of Medicine and Surgery, was alleged against him, nor is there any evidence in the record which would have justified such a charge, or which tends to cast any reflection upon his personal honesty. It is equally proper, however, to remark that the charges of 'culpable inefficiency in the performance of duty' and 'neglect of duty' are fully sustained by the evidence. The proof shows that the established routine of business in the Bureau of Medicine and Surgery, including the various steps required by the regulations to be taken in making purchases of supplies and in paying for the same, was such that the exercise of ordinary care on the part of Dr. Wales, as chief of the bureau, would have been sufficient to arrest at an early date, if it could not have been wholly prevented, the fraudulent acts of his subordinates in the bureau. When he assumed charge of the bureau, as chief, he became officially bound to enforce, so far as practicable, an honest as well as diligent performance of duty by his subordinates, and also became responsible for a proper supervision of their conduct. This he failed to do. The facts and the degree of punishment proper in the case have received the careful and laborious consideration of a most eminent court of naval officers. The proceedings, findings, and sentence of the court in this case are approved."

Dr. Thomas B. Hood, who has so long and so efficiently performed the duties of Medical Referee of the Pension Bureau, was removed this week, and Dr. Campbell, of Cincinnati, appointed in his place. It is difficult to see what public policy could dictate the removal of one so well fitted by education and long experience to settle the intricate and far-reaching questions submitted to the medical branch of the bureau.

Dr. C. V. N. Callan, of the Providence Hospital staff, has been seriously ill for the last month, and his friends have feared that his return to duty would be permanently prevented.

Laparotomy with suture of the intestines was recently performed at the Providence Hospital by Dr. John B. Hamilton. The patient, a young mulatto, was shot in the abdomen three weeks ago. The wound was inflicted by a pistol carrying a ·32 caliber ball. The missile severed a small artery in the mesentery, and made eleven wounds in the small intestines and two in the ascending colon, and remained in the bowel. The operation was performed three hours after the accident. The artery was tied and the wounds were stitched with Lembert's suture. Fæces were passed by the natural channel on the seventh day, and on the twentieth day the patient was allowed to sit up, the abdominal wound having healed. The ball was passed with the fæces on the twelfth day.

Consul Mason, in a recent report to the State Department on the last year's outbreak of cholera at Marseilles and vicinity, states that it is now apparently settled that the cholera of 1884 was kindled at Marseilles by the clothing brought to that city in the trunk of a young student coming from the Lycée at Toulon.

In regard to the outbreak at Omagues, in the Department of Basses-Alpes, he states that "on the 10th of July, 1884, there arrived at Omagues a young servant-girl who had been in service at Marseilles. Soon after her arrival she washed some linen, which *had been in contact with a cholera patient* at Marseilles, in the Jabron, *a creek which supplies the village with water.* From that imprudence sprung the contagion which decimated that unfortunate community and spread death throughout the valley of the Jabron *below* Omagues, while the inhabitants of the same valley above the village escaped."

NEW YORK, SATURDAY, AUGUST 8, 1885.

VACCINATION AFTER THE BEGINNING OF SMALL-POX.

SOME weeks ago, commenting on a paper, by Dr. Eccles, of Brooklyn, published in this journal, we had occasion to express an opinion which we then supposed, and still believe, to be supported by overwhelming testimony, to the effect that it was useless to vaccinate a person already affected with small-pox. We were aware that an impression to the contrary existed in the minds of many of the profession, but we were quite unprepared for such statements as we find in a report by Dr. J. H. Rauch, the able and painstaking secretary of the Illinois State Board of Health, submitted to the board at its quarterly meeting, held July 2 and 3, 1885. Dr. Rauch quotes from previous published writings of his own as follows: "It has now come to be understood that vaccination has a positive therapeutic value, as well as prophylactic power, and where it is too late to exert the latter there may still be sufficient time to make the former available, provided the virus used act promptly. Thus, if a patient be vaccinated during the febrile stage, and the vaccination progress normally—there being nothing antagonistic between the two diseases, variola and vaccinia, to prevent such normal progress—the areolar stage of vaccination will be reached before the dangerous tenth day of the variolous disease; and, as has been repeatedly witnessed, the graver disease will be aborted, jugulated, or materially modified." Again, he says: "It is never too late to vaccinate."

This is a question that only observation can settle, and our conviction is that observation did settle it long ago. The late Mr. Marson, whose experience was simply enormous, is quite explicit on this point. In his article on Small-pox, in Reynolds's "System of Medicine," he says: "Suppose an unvaccinated person to inhale the germ of variola on a Monday; if he be vaccinated as late as on the following Wednesday, the vaccination will be in time to prevent small-pox being developed; if it be put off until Thursday, the small-pox will appear, but will be modified; if the vaccination be delayed until Friday, it will be of no use, it will not have had time to reach the stage of areola, the index of safety, before the illness of small-pox begins; this we have seen over and over again, and know it to be the exact state of the question. Re-vaccination will have effect two days later than will vaccination that is performed for the first time, because re-vaccinated cases reach the stage of areola two or three days sooner than in those persons vaccinated for the first time."

Marson's article has been widely read, and the particular statements we have here reproduced have been extensively quoted, without, so far as we are aware, the accuracy of the latter having ever before been challenged by a competent ob-

server. But Dr. Rauch does not rest his contention on theory or dicta; he adduces certain facts that have come to his own knowledge. These facts relate to a recent outbreak of the disease in Mound City, Illinois, in which one hundred and forty-four cases occurred. Of those attacked, one hundred and twenty had never been vaccinated prior to actual exposure. After exposure to cases in their respective families, fourteen of this number were vaccinated—the exposure having lasted from three days to "about a week." Of the remaining one hundred and six, thirty-eight died, the mortality rate being 35·84 per cent. of the wholly unvaccinated. Only one ("a confirmed epileptic," twenty-five years of age, vaccinated in childhood) died, out of the thirty-seven vaccinated before exposure—the mortality rate in this class being, therefore, less than three one-hundredths of one per cent. All the fourteen who were vaccinated only after exposure recovered. Interesting statistics are then given as to the average duration of the disease in the several classes.

These statements appear to be very much to the point, and, however at variance they may be with general observation, we are disposed, considering the high source from which they emanate, to look upon them as of great importance. There is a point, however, on which more specific information would be of value—as to how many of the fourteen had been exposed for only three days, and how many for "about a week," before being vaccinated. Moreover, it is not certain that a person necessarily imbibes the contagium the first day that he is exposed to it, or the second day, or any particular day. Nor does it appear that any of the fourteen had shown signs of actually having the disease before they were vaccinated. Much as we defer to Dr. Rauch's judgment, therefore, we can not admit that in this instance the facts sustain his statement that "it is never too late to vaccinate."

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 4, 1885:

DISEASES.	Week ending July 28.		Week ending Aug. 4.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	1	0	0
Typhoid fever	16	6	27	5
Scarlet fever	29	6	23	4
Cerebro-spinal meningitis	2	1	2	2
Measles	34	8	21	4
Diphtheria	34	21	33	17
Small-pox	1	1	2	0

The Health of the State of New York.—The State Board of Health's "Bulletin" for the month of June shows a total reported mortality of 6,204, of which 40 per cent. were of infants. The proportion of deaths in each thousand was 238·55 from zymotic diseases, 109·61 from diarrhœal diseases, 51·42 from croup and diphtheria, 103·64 from acute respiratory diseases, and 131·20 from consumption.

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office August 4th: *Cardenas, Cuba.*—For the week ending July 18th: Free from epidemics; no cholera or yellow fever. *Curaçoa, W. I.*—For the same week: No cases of infectious disease. *Havana, Cuba.*—For the week ending July 22d: About 22 cases and 3 deaths from yellow fever; typhoid fever prevalent. *Matanzas, Cuba.*—For the same week: No cholera or yellow fever; intermittent fever prevalent. *St. Thomas, W. I.*—For the second quarter of 1885: 4 deaths from yellow fever among soldiers in garrison prior to May 1st, when detachment was removed; no cases since. June 23d, quarantine was established against all Spanish ports, and the importation of rags, padding, wool, hair, and hides prohibited. *Laguayra, Venezuela.*—For the week ending July 18th: Free from infectious diseases. *London, Eng.*—For the week ending July 11th: 101 cases of small-pox, and 21 deaths; 101 deaths from diarrhœa and dysentery, and 3 from simple cholera. *Paris, France.*—For the week ending July 18th: Small-pox, 41 cases, 1 death; typhoid fever, 199 cases, 38 deaths. During the week ending July 11th there were 40 cases of small-pox and 5 deaths; typhoid fever, 146 cases and 27 deaths. *Lisbon, Portugal.*—May 9th to 23d: 6 deaths from small-pox; otherwise free from infectious diseases. *Trieste, Austria.*—For the week ending July 4th: 3 deaths from small-pox; diphtheria prevalent. *Valencia, Spain.*—For the week ending July 11th: Cholera, 1,747 cases and 964 deaths. The epidemic is reported as spreading still, but becoming less virulent. *Venice, Italy.*—For the week ending July 4th: 5 deaths from small-pox; diarrhœal diseases prevalent. *Bombay, India.*—For the week ending June 23d: 2 deaths from cholera; general sanitary condition good.

English Comments on the Congress Question.—Until now, the "Medical Times and Gazette" has been almost the only European journal to give its readers anything like an adequate idea of the deplorable status of the matter of the International Medical Congress in this country. In its issue of July 25th it quotes from a number of American journals, and says editorially: "The leaders of the profession both in Boston and Baltimore have followed the lead of the Philadelphians and withdrawn from the Congress, and it is not unlikely that their example may spread to other cities, though indeed enough has already been done to turn the meeting of 1887 into what an American contemporary, drawing its illustration from our common history, appositely terms a 'rump' Congress. The only hope is that the American Medical Association will be startled back to its senses by the strong and decisive action of the profession in Philadelphia, Boston, and Baltimore, and will make haste to retrace its steps. It may be taken for granted that not even the leaders of the malcontents, and certainly not the members of the association at large, realized that the result of their action would be destruction to the Congress of 1887 and danger to its successors. Such an event was probably far from their calculations. They simply reckoned without their host, *i. e.*, their leaders, and if they are wise they will cast another reckoning, this time with due regard to the said host."

Homœopaths in the British Medical Association.—In the report of the Council, presented at the recent meeting at Cardiff, and published in the "British Medical Journal," we find this statement: "The Council have had under their consideration the subject of admission and retention of homœopaths as members of the association during the past year. An inquiry has been made throughout the thirty-three branches, and the result has been that there is evidence to the effect that a large majority of the members are adverse to the admission of homœopaths as members, but an equally large proportion are opposed to the idea of the expulsion of those members who have already gained admission into the ranks of the association."

The Lehigh Valley Medical Association will hold its fifth annual meeting at Quakertown, Pa., on Wednesday, the 19th inst. The programme includes an address on "The Proper Organization of Local Boards of Health," by Dr. Benjamin Lee, and one on "The Treatment of Joint Diseases by Rest," by Dr. De Forrest Willard.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 26, 1885, to August 1, 1885:*

Bill, Joseph H., Major and Surgeon, U. S. A. Died at Yonkers, N. Y., July 21, 1885.

McDougall, Charles, Lieutenant-Colonel, U. S. A. (retired). Died at Fairfield, Va., July 25, 1885.

DeWitt, Calvin, Captain and Assistant Surgeon. Promoted to major and surgeon, vice Bill, deceased, to take effect from July 21, 1885.

Ives. Franois J. Appointed assistant surgeon with rank of first lieutenant, to rank as such from July 25, 1885.

Girard, A. C., Captain and Assistant Surgeon. From Department of the East to Department of the Columbia. S. O. 170, A. G. O., July 27, 1885.

Ebert, R. G., Captain and Assistant Surgeon. From Department of the Columbia to Department of the East. S. O. 170, A. G. O., July 27, 1885.

Tesson, L. S., Captain and Assistant Surgeon. Ordered from Fort Stockton, Texas, to Fort Davis, Texas. S. O. 90, Department of Texas, July 27, 1885.

Carter, W. F., Captain and Assistant Surgeon. Ordered for duty as post surgeon, Fort Stockton, Texas. S. O. 90, Department of Texas, July 27, 1885.

Appel, A. H., Captain and Assistant Surgeon. Ordered for duty with U. S. troops, forming portion of guard of honor over remains of Ex-President General Grant, at Mt. McGregor, N. Y. S. O. 36, Division of the Atlantic. July 29, 1885.

Gorgas, William C., Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect about August 10, 1885. S. O. 169, A. G. O., July 25, 1885.

Society Meetings for the Coming Week:

Monday, *August 13th:* Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

Tuesday, *August 14th:* Medical Society of the County of Rensselaer, N. Y.; Newark and Trenton, N. J., Medical Associations (private).

Wednesday, *August 15th:* New Jersey Academy of Medicine (Newark).

Thursday, *August 16th:* New Bedford, Mass., Society for Medical Improvement (private).

Letters to the Editor.

THE MEDICAL MUDDLE.

Fort Buford, D. T., *July 25, 1885.*

To the Editor of the New York Medical Journal:

Sir: It is not graceful to apply such terms as "organized villainy" and "crowning act of infamy" to the American Medical Association, as was done in your editorial of July 11th. Let us see: "Villany, n. Extreme depravity. Atrocious wickedness." "Infamy, n. Total loss of reputation." Is our great A. M. Ass. depraved or totally wicked, or has it lost anything?

I once knew a good old man who was noted for wealth and Christian meekness in a community where both were scarce. He had a pet chicken, which was being raised "by hand," as it were. This chicken, early in its career, showed a strong tendency to consider itself "one of the family." Its frequent visits to the parlor made it a disturbing element. On the occasion of one of these visits, the old man, who had been dozing before a bright fire, called a negro servant to drive the chicken out. The servant, with white apron spread before him, made a dash at the chicken, and so startled it that it ran into the blazing fire upon the hearth. The old gentleman gazed upon the catastrophe with more of horror than commiseration depicted upon his features, and, after mature deliberation, remarked with great gravity, "You're a fool!" It was the first and only piece of severity he was ever known to be guilty of, although the owner of two or three dozen slaves.

I don't know why the action of the A. M. Ass. should recall this incident of my childhood. The feelings with which I have contemplated that action have not been all commiseration, but "organized villainy" and "crowning act of infamy" were never suggested to my thought. Instead of guile, I have noticed, besides bile, that absence of intelligent comprehension which led the chicken—but I have said I did not know why the action of the A. M. Ass. reminded me of the chicken incident.

I had supposed that the idea of the Congress was an associated effort of the leading medical minds of the world to evolve something by which mediocrity might be benefited, and the leading minds refreshed and encouraged for still greater achievements. The idea that local geographical divisions in our country could have anything to do with such a Congress was, to me, the embodiment of—why did you not, by the way, think of that word *imbecility?* It would have obviated the necessity of such strong terms as "villainy," "infamy," etc.

I could never understand why well-earned obscurity should desire to obtrude itself upon the assembled wisdom of the world. I yield to no man in the possession of that amiable quality; but, before I would allow myself thrust into such company in any official capacity, I would apply for a "sick leave." If left without constraint, I might slide in at a side-door and listen to the speeches in German and Russian, but nothing more.

Large bodies are apt to act with more difficulty than wisdom, and are only necessary when the political and religious liberty of all are concerned. The original committee, being intelligent and wieldy, was doing its work well. If it had been let alone, gratifying success seemed reasonably sure. As matters now stand, ignoble failure is much to be feared. There ought to have been no two opinions about our duty, or the duty of the committee, to put forward: 1. Our men of international reputation. 2. Our men of national reputation. 3. If more were needed to round off with, the best local material. But no geographical thought should have entered any man's head, nor would have, if nature had not abhorred a vacuum.

S. S. Turner, M. D., A. A. Surgeon, U. S. Army.

THE DISINFECTION OF RAGS.

August 5, 1885.

To the Editor of the New York Medical Journal:

Sir: In the "Medical Journal" of August 1st Major Sternberg states, in a letter addressed to you, that he has nothing to do with the fight between the paper manufacturers and the health officers, who insist upon the disinfection of rags from cholera-infected districts. I am not aware that any such fight exists.

They (the paper makers) not only *do not object* to rags from infected ports being disinfected, but would prefer (in deference to public opinion) that their importation (from such ports) should be entirely prohibited. The only contest the paper manufacturers have with the health officers is about rags from healthy ports. Last winter a patent was obtained for a process for disinfecting rags; a few days afterward an order was issued that all rags shipped after January 1st should be disinfected; this order was revoked by the present Secretary of the Treasury.

No such patent or order was ever before issued in this or any other country. What the paper makers object to is that, while there is no case on record of cholera having been conveyed in rags, they should be compelled to subject their material, under the pretext that it is dangerous, to an expensive and (as they believe) injurious and unnecessary process.

The estimated annual consumption of rags in this country is 270,000 tons. The charge for "disinfecting" is $5 a ton; this would make quite a handsome revenue.

By publishing this you will much oblige yours, etc.,

Augustine Smith,

Vice-President of the American Paper-Makers' Association.

DR. DIXON JONES'S UTERINE APPLICATOR.

Brooklyn, *August 3, 1885.*

To the Editor of the New York Medical Journal:

Sir: The cut accompanying the description of my applicator, in your issue of August 1st, entirely fails to give a proper idea of the instrument. By some mistake, the instrument-maker failed to send the cut intended to accompany the description. The forceps has a double curve—one corresponding to that of the normal parous uterus, the other a compensatory pelvic curve, which facilitates any manipulation in which it is used.

Yours, very respectfully,

C. N. Dixon Jones.

Proceedings of Societies.

NEW YORK OBSTETRICAL SOCIETY.

Meeting of February 17, 1885.

Dr. Walter R. Gillette in the Chair.

Recurrent Tumor of the Breast. — Dr. B. F. Dawson showed a tumor which he had removed a few days before. Five years ago an enlargement appeared in the patient's right breast. The mass was excised, but soon recurred, so that it was necessary to repeat the operation seventeen times; the last operation was performed about a year ago. Soon after that the patient began to be troubled with excessive leucorrhœa, and for six months past she had had repeated hæmorrhages, attended with a gradual decline in her health and strength, so that a suspicion of malignant disease of the uterus was aroused. Six months ago there was a recurrence of the mammary growth at the site of the last operation. Dr. Dawson saw the patient one month ago. The tumor then presented the appearance of a large dark bleb. The os uteri was patulous and its edges were ragged, but there was no hæmorrhage at that time. The uterus was movable, and there were no evidences of infiltration around it. Dr. Sands now saw the patient in consultation, and regarded the tumor as a myxo-sarcoma. She improved so much that Dr. Dawson operated about three weeks ago. She had recovered rapidly and was now able to walk about. Her uterine condition had improved, but, if the hæmorrhages returned, he would consider the question of a radical operation. (A subsequent microscopical examination showed epithelioma of the cervix.)

Sarcoma of the Uterus.—Dr. Dawson also showed a quantity of soft brain-like material which he had removed from the uterine cavity of a patient at the Woman's Hospital. She had had constant leucorrhœa for four years, with repeated hæmorrhages during the past three months. The discharge always had a very offensive odor. He found an irregular patulous os, from which protruded a dark, friable mass, which bled easily on being touched. The uterus was enlarged and soft, but freely movable. The diagnosis seemed to lie between sloughing fibroid and sarcoma. The cervix was divided and the interior of the uterus was thoroughly scraped with the spoon-saw (which was used as a curette). Although the patient had showed symptoms of septic poisoning before the operation, she recovered perfectly and was now comfortable. It would probably be necessary to remove the uterus eventually.

Dr. Dawson remarked that these cases were both interesting from the fact that if the conditions had been recognized at an early day much trouble might have been saved.

Dr. H. C. Coe said that he had examined the second specimen and found it to be round-celled sarcoma.

Dr. A. Jacobi asked if any enlargement of the axillary glands had been observed. The reply was in the negative. Dr. Jacobi said that he had asked this question because he had the impression that sarcoma was rarely attended by any considerable affection of the neighboring glands. He further stated that sarcoma of the uterus sometimes bore a close resemblance to fungoid growths. He recalled the case of a woman, forty years of age, from the interior of whose uterus he had removed with a common soup-spoon a cauliflower mass as large as a man's fist, which proved to be round-celled sarcoma. No secondary deposits existed, so far as could be ascertained; in fact, sarcoma might run a long course without the formation of metastatic growths.

Dr. P. F. Mundé mentioned the case of an Irishwoman who entered his service at Mt. Sinai Hospital, complaining of frequent uterine hæmorrhages and a constant offensive discharge. The uterine cavity was found to be four inches in depth and was filled with a soft mass which broke down under the finger. As the patient was too weak at the time of entrance, he intended to build up her strength and then to scrape out the cavity with a Simon's sharp spoon and subsequently swab it out with chloride of zinc, but an operation was declined.

Dr. Jacobi asked, with reference to the mammary tumor, if it was not rather unusual to have a complete absence of glandular enlargement after the growth had been so frequently removed.

Dr. Dawson thought that perhaps the tumor had always been removed so early that there was no time for the glands to enlarge.

A Shot-Perforator.—Dr. C. Cleveland presented a modified shot-perforator, in which a spring was so arranged that the shot were disengaged from the pin as the forceps opened.

A Uterine Drainage-Tube.—Dr. W. G. Wylie showed a uterine drainage-tube of hard rubber for use after dilatation of the cervix, or whenever it was desirable to maintain patency of the canal. He said that he used six sizes of the instrument, there being three variations in the length and three in the diameter. He maintained the following advantages for the tube: 1. Having a bulbous extremity, it could not slip out of the canal. 2. The groove along its side allowed of free drainage. 3. The curve was such that it adapted itself perfectly to the shape of the uterus. 4. There was a knob at the lower end,

which could be held with a forceps and the tube easily withdrawn.

Dr. J. B. Hunter asked when this instrument was indicated. The answer was, when it was necessary either to drain the uterus or overcome stenosis.

Dr. Mundé thought that a straight stem could be introduced perfectly well if the os was dilated thoroughly and the anterior lip was then drawn down with a tenaculum.

Dr. Hunter remarked that Dr. Sims origiually used a straight tube, but subsequently modified it.

Dr. Dawson and Dr. Perry thought that the cervical mucous membrane might become entangled in the slot at the side of the stem, so that it would be impossible to withdraw it.

Dr. Wylie said that this never occurred after proper dilatation. He thought that the cervix was stretched during the attempt to introduce a straight stem. He had been led to adopt this form of stem from observing how often it was necessary to hold the other varieties *in situ* by means of tampons. He was of the opinion that in many cases the plug had not been passed through the internal os at all.

Dr. Cleveland asked if stems were not sometimes forced out even after they had been introduced through the os internum.

Dr. Wylie thought not. He subsequently admitted that they might be expelled by uterine contractions.

Dr. Mundé differed with Dr. Wylie, and thought that he had frequently introduced laminaria tents through the os and had seen them come out again, simply because they were slippery.

Dr. Wylie thought that a distinction should be drawn between *slipping* and *rebounding*.

Silvered Copper Wire.—Dr. Hunter showed a specimen of silvered copper wire which possessed all the advantages of solid silver wire and yet cost only about one twentieth as much. It was less brittle than silver.

B. McE. Emmet, M. D.,
B. F. Dawson, M. D.,
H. C. Coe, M. D., *ex officio*,
Committee on Publication.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of June 10, 1885.

The President, Dr. John A. Wyeth, in the Chair.

Exsection of the Knee.—Dr. J. H. Ripley presented an Italian, twenty-eight years of age, who was admitted into Charity Hospital September 14, 1882. There was no history nor evidence of venereal disease. He had always been well until four years ago, when he had an attack of rheumatism, suffering continuously from severe pains in the left knee joint, which was very hot, but not swollen. This attack continued for about one year, and then disappeared of itself. September 2, 1882, the patient slipped on a banana-peel and injured the left knee, which soon increased to twice its natural size, and became very hot and painful. Twelve days later he entered Charity Hospital, and was treated for rheumatism in a medical ward for three months, when he was transferred to a surgical ward. Extension was employed for two months, in conjunction with the local application of liniments, etc., and internal remedies. Extension was then discontinued, and a succession of plaster-of-Paris splints applied, together with the use of electricity, etc. Although there was absence of crepitus, and several surgeons were in doubt as to the propriety of exsection, Dr. Ripley concluded to do the operation, as it seemed to offer the patient the only chance of relief. The bones of the joint were very extensively diseased. The patient made a good recovery, with two inches shortening. The interest of the case centered in the fact that the man had suffered for nearly three years with inflammation of the knee, there being no suppuration, and at the end of that time the pathological condition was such that several surgeons were in doubt as to the propriety of exsection. The reason why friction was absent was that at no one point were both of the opposing bones roughened. A second point of interest was the illustration of the reparative power of diseased bone. A third point of interest concerned the use of wires. Dr. Ripley thought they did little or no good, and they gave him a great deal of trouble in removing them. He referred to another case of exsection under like circumstances, done about ten years ago, in which the patient was longer in recovering from the fact that the bones were not made immovable.

The President remarked that this case afforded strong evidence in favor of exsection as against the old method of treatment by amputation. In the latter case the death rate had been placed at twenty-five per cent. He had not seen a case in which death resulted from exsection. He referred to some cases in which he had done exsection the past winter, and said he did not use wires, for the limb could be rendered immovable without them. If wires were used, it was unnecessary to remove them afterward.

Suppurative Endocarditis.—Dr. R. Van Santvoord presented the heart and great arteries removed from the body of a man, forty-six years of age, who was admitted into the hospital March 28th. His father had died suddenly after a few weeks' illness, the nature of the trouble being unknown. His mother had died suddenly of heart disease, aged sixty-three. The patient, when a child, had had measles, scarlet fever, and smallpox, had had a chancre without secondary manifestations, and had been a hard drinker. He had suffered from rheumatism and from swelling of the feet at night. There were aortic and mitral regurgitant murmurs, the apex beating in the sixth intercostal space. When admitted, he was suffering from rheumatism, the attacks recurring during his stay, with exacerbations of temperature, and finally exhaustion. He had become apathetic, and his memory failed. At the autopsy a small bony growth was found impinging upon the brain between the second and third frontal convolutions, about half an inch in front of the ascending frontal. There was a certain amount of pachymeningitis hæmorrhagica, chiefly over the left hemisphere; the membranes were generally opaque; most of the vessels at the base of the brain showed considerable atheroma. There were lesions in other organs, the result of alcoholism, but the lesion of chief interest existed in the heart. There were the remains of old pericarditis, the ventricles were somewhat dilated, and the muscular substance had the gross appearance of fatty degeneration. On the leaflets of the aortic valve were masses of vegetation, surrounding two perforations of the valve, of about the size of a crow-quill. The third leaflet was somewhat atheromatous, but had no vegetations. There was also a rough spot of the size of a three-cent piece on the inner surface of the heart, forming a pocket. A small mass of vegetations was found on one of the leaflets of the mitral valve. The aorta showed advanced atheroma. The sphygmographic traeing had been that said to be characteristic of a combination of aortic regurgitation with atheroma of the arteries.

Congenital Deformities.—Dr. A. Jacobi showed a boy, aged seven years, who presented certain congenital deformities, but was in normal health. The right upper extremity was normal. On the left hand there were but three fingers, the index and little fingers being absent, together with their corresponding metacarpal bones. The left ulna was 14 ctm. long, and the right one 16·75; the left elbow joint was imperfectly formed, allowing of only partial supination. The lower extremi-

ties presented symmetrical malformations excepting in the following respects: The left foot was half an inch shorter and was smaller than the right; the right thigh was longer than the left by about 4 ctm. The movements of the right foot were much freer than those of the left. The patella was absent on the left side, and imperfectly formed on the right. The right leg was 28, the left 27 ctm. in length. On the left foot the second and third toes were slightly raised. The chest showed some signs of rhachitical development, most marked on the left side. The head and face were nearly symmetrical.

His sister, a baby, aged three years, had a congenital deformity of the right leg and foot. The tibia had an anterior curve, and at about the junction of the middle with the lower third there was a longitudinal scar half an inch in length. There was decided eversion of the foot, with absence of the fibula. There were but two toes, one being the great toe, the other apparently a blending of two toes. There were three metatarsal bones, the great toe articulating with the first, and the second toe with the two others. The right limb, down to the knee, seemed to be perfect. It was impossible to straighten the leg on the thigh, because of some malformation in the knee joint. The leg turned outward when it was straightened as far as possible. The right leg was shorter than the left by an inch and a half, being eleven inches long. There seemed to be no anterior tibial artery. The right foot was shorter and smaller than the left. As to the bones entering into the formation of the tarsus, it was impossible to state positively, but the cuneiform bones seemed to be absent. The right patella seemed to be somewhat smaller than the left, and was placed a little externally to the normal position. The three metatarsal bones articulated with the scaphoid and cuboid. The speaker had seen as many as three or four cases of absence of the fibula, there being a scar on the leg, which one might suppose resulted from an injury at a period of intra-uterine life when the skin was only partially developed.

Volvulus of the Sigmoid Flexure.—Dr. Frank Ferguson presented a distended and dried gut, showing volvulus of the sigmoid flexure. The patient, a Russian, aged thirty-seven years, had complained for several years of abdominal pains and cramps, which would pass away to return again. On the 27th of February last an attack had lasted three days, when he sought relief in the hospital. It began with a chill, followed in a short time by nausea and vomiting, there being very severe and continuous pain in the abdomen. He rapidly failed, and died four hours after admission. The autopsy showed enormous distension of the gut, with twisting of the sigmoid flexure, which was blackened with hæmorrhage. The obstruction was complete.

Dr. Waldstein thought it was not infrequent to find at the autopsies of old subjects, with a large amount of adipose tissue in the peritonæum, a turning of the gut, almost amounting to a complete twist and obstruction, with great distension of the colon co-existing.

Dermoid Cyst near the Coccyx.—The President presented a tuft of hairs, obtained in the case of a patient twenty-two years of age, who came for treatment of a supposed fistula starting eighteen months before in what he called a boil near the coccyx. The sinus led down to an abscess, and no communication with the rectum was apparent. A little pimple, looking like a comedo, attracted attention, and, being explored with a probe, was found to lead to a small cavity. With a little force the probe was made to penetrate into the old abscess. In the cavity was a tuft of hair, resembling that of a camel's-hair pencil. The President thought it was undoubtedly a dermoid cyst, and, so far as he knew, the case was unique.

Dr. Ferguson asked if congenital cysts in this locality were not rather common. He had examined two specimens of congenital cysts situated over the sacrum which contained ciliated epithelium and cholesterin. No hair was present.

Reports on the Progress of Medicine.

GENERAL MEDICINE.

By ALEXANDER DUANE, M. D.

The Morbid Anatomy of Diabetes.—The summing up of Windle's examination ("Dublin Jour. of Med. Sci.") of all accessible records of autopsies held in cases of diabetes mellitus is that no one lesion is present with any degree of constancy, and, further, that no one organ is involved in more than half the cases in which the condition of that organ has been ascertained. Thus, in 184 cases in which the brain was examined, it was found normal in 91, and in the remaining 93 the most diverse lesions were discovered. Lesions affecting the medulla and the fourth ventricle were present in 23 of these cases. So, also, among 58 cases in which the spinal cord was examined, only 25 showed any abnormity. On the other hand, out of 333 cases, only 75 presented a normal condition of the lungs, while rather more than one half of the whole number displayed the lesions of pulmonary phthisis. It is to be noted that these pulmonary lesions do not appear to be the result of the deposition of tubercle, and for their origin seem to be dependent upon some change taking place in the nervous system. Fat embolism of the lungs, although described by some, seems to be of rare occurrence. Enlargement and congestion of the liver are frequent accompaniments of diabetes, but the microscopical appearances are not characteristic. The same may be said of the renal changes. The pancreas, again, was affected in more than half of the cases in which the condition of the organ was noted, the lesion being usually of an atrophic nature. Lesions of the other organs are noted, but are still more inconstant in their appearance. These are all tabulated in considerable detail in the original paper.

Diabetic Coma.—Lindsay (*Ibid.*) brings little that is new to add to our confessedly imperfect knowledge of diabetes. He briefly dismisses most of the current theories as to the origin of diabetic coma, believing them all to be unproved, although he inclines most favorably to the toxæmic hypothesis. His own observations, with those of others, show that coma terminates about half of the cases of diabetes, being relatively more frequent in the young and in cases of acute coma, more particularly those uncomplicated by pulmonary disease. [That a rapidly fatal course with death from coma is usual in young subjects has been shown already by Schmitz, who has statistics of six hundred cases of diabetes.]

A Disease of Auerbach's and Meissner's Plexuses.—Blaschko ("Arch. f. path. Anat. u. Phys. u. f. klin. Med.") has described two cases, in both of which there was extreme fatty degeneration of the sympathetic plexuses in the walls of the intestine (plexuses of Auerbach and Meissner). Only one case presented a well-defined clinical history, the symptoms being those of extreme and progressive anæmia and profound disturbance of the digestive functions, with abdominal pain, but without any characteristic change in the blood suggestive of pernicious anæmia or of leucocythæmia. There was marked atrophy of the intestinal wall, and the fact that in other cases where this atrophy existed, and where a sufficient cause for its existence was present, no alteration of the sympathetic plexuses was found, seems a proof that the sympathetic lesion in this case was the cause, and not the effect, of the intestinal atrophy.

Œdema from Vaso-motor Paralysis.—Jankowski's experiments upon animals (*Ibid.*) tend to prove that vaso-motor paralysis is an important factor in the production of œdema; and that, while scarcely of itself sufficient to excite this condition without an accessory hydræmia, its influence must be called into account for most of the cases of œdema occurring in cachectic conditions. The fact that transudation from the vessels may thus be largely dependent upon the state of the peripheral nerves, and hence upon alterations of the nervous centers affecting this state, will also serve to explain the existence of urticaria and of the

acute circumscribed œdema of Quincke (acute rheumatismal œdema), which undoubtedly have their origin in the central nervous system.

Diabetes Insipidus.—Weil (*Ibid.*) has, with extraordinary patience and industry, followed out the family history of a patient afflicted with diabetes insipidus, and has found that in his case it was undoubtedly an hereditary malady, many of his ancestors and immediate relatives being victims to it, or, to use their own phraseology, being "water-drinkers." The disease first appeared in the family records in the great grandfather, who had five children, of whom three were affected like himself. Of twenty-nine grandchildren, seven were "water-drinkers" and nine died in infancy, before the disease had a chance to show itself. There were fifty-six great grandchildren, and twelve of these were the subjects of diabetes. It is to be remarked that all who escaped having the disease transmitted the same immunity to each one of their children and grandchildren; so that atavism would seem to be the exception in the transmission of this form of diabetes. The author's facts, the collection of which must have cost him very great expense of time and trouble, are summed up in a neat genealogical tree, showing the relationships between the diabetic ancestor and his ninety descendants, as regards both the ties of blood and the more recondite associations involved in the transmission of the disease.

Intestinal Neuroses.—Cherchevsky ("Rev. de méd.") has collected several cases which he regards as examples of tonic spasm of the circular muscle-fibers of the intestines. This accident, which occurs more especially in persons of intellectual habits and sedentary modes of life, is characterized by suddenly appearing enormous tympanitic distension of the abdomen, with a considerable degree of pain and tenderness, a sense of epigastric oppression and of dyspnœa, violent griping pains and constant desire to go to stool with inefficient expulsive efforts, and the passage of only a small amount of fæcal matter in the form of bullet-like scybala or of small compressed cylinders. These symptoms last a few hours, or even some days, and then suddenly disappear. In the intervals between the paroxysms the patients enjoy excellent health, their appetite is good, and their only complaint is of more or less persistent tympanites, with constipation and frequent eructations of odorless and tasteless gas. The paroxysms are induced by intellectual effort, mental excitement, violent emotions, etc. This, together with the suddenness of the appearance and disappearance of the symptoms and the character of the latter, leads the author to the belief that in this condition we have to do not with a state of intestinal atony, but with a state of localized intestinal spasm, producing sudden accumulations of gas with the associated phenomena of colic, tenesmus, and constipation. The results of treatment are corroborative of this view, as the constipation and tympanites yield readily to opium and belladonna, while cathartics, which should ameliorate the symptoms, if due to atony, only aggravate them.

The Virulence of Tuberculous Matter.—Martin and Parrot (*Ibid.*), in experiments which seem to be conclusive, have found that no one of the so-called antiseptics—carbolic acid, creasote, corrosive sublimate, bromine, salicylic acid, or oxygenated water—even in the most concentrated solutions and the most complete and prolonged contact, can be relied upon to destroy the virulence of tuberculous matter. The only agent which acts certainly in this way is heat, and the surest means of disinfection in a hospital or apartment is the introduction of air heated to 125° C., and carried into every corner and crevice. But, so far as any feasible means for attacking the tuberculous organism in the human system are concerned, the author's experiments are completely negative.

Diabetic Neuralgia.—The occurrence of neuralgia in diabetic subjects, and depending apparently upon the diabetic diathesis for its existence, has been noticed by several writers within the last two or three years. Cornillon (*Ibid.*) has collected the histories of twenty-two instances of this association of neuralgia with diabetes; eight of these cases, including two contributed by himself, have been very fully described; the histories of the other cases are more meager. The characteristics of diabetic neuralgia, judging from the description of these twenty-two cases, are well marked, and render the diagnosis of the complaint easy. Such neuralgias are distinguished by their spontaneity, no cause, either immediate or remote, except the glycosuria, being discoverable; by their intensity, hardly paralleled in any other variety of pain; by their tendency to a symmetrical development (noted in eighteen out of the twenty-two cases); and by the obstinacy with which they resist any form of treatment except that addressed to the relief of the causal condition—the diabetes itself. They show a tendency to attack the regions supplied by the sciatic nerve, although the face and other parts of the body are also occasionally affected. They are associated with marked tenderness to pressure over the course of the nerve which is the seat of the pain; and motion of the muscles in the vicinity of the nerve, as well as variations of temperature, greatly aggravates the suffering. The causation of this rather infrequent form of neuralgia is still obscure. The author rejects the hypothesis of Rosenstein, that it is due to congestion of the abdominal viscera, on the ground that the latter is so often present without the co-existence of any neuralgic or any diabetic symptoms. The theory that it is due to an excess of sugar in the blood is disproved, he thinks, by the fact that in some of the cases the glycosuria is very moderate, and that, although in some instances the intensity of the symptoms is proportional to the degree of glycosuria, this is by no means the universal rule. Cornillon's own view, which we believe to be open to the same objections that he urges against these other theories, is that diabetic neuralgia is a manifestation (as he holds diabetes itself to be) of a gouty diathesis, and that such a neuralgia is the direct result of a condition of uricæmia. The decision of this question must, however, undoubtedly await more extended investigation and the analysis of a greater number of cases than the author has been able to collect.

Pernicious Anæmia in Children.—Kjelberg ("Arch. f. Kinderheilk.") describes a case of pernicious anæmia occurring in a child five years of age and running a very rapid course, without remissions, until death occurred, only a month and a half after the inception of the disease. The case is highly interesting as constituting, with one other, the only certainly known instances of pernicious anæmia in childhood. The whole account is sufficiently full and accurate, and, with the confirmatory evidence of the autopsy, leaves no doubt as to the correctness of the diagnosis.

The Relations of Scrofula and Tuberculosis.—Albrecht (*Ibid.*) insists anew upon the pathological identity of tuberculosis and scrofula, and, from recent literature, gives a host of instances where tubercle bacilli have been found in scrofulous formations. The practical bearing of the connection between these two morbid states is evident; and, if this connection were only a probable one, it would still claim our attention in view of the great prevalence of scrofula and the fatality of tuberculosis. If there is a chance that the former can develop into the latter, or even if we are limited to the certainty that the former leaves the system in a condition suitable for the development of the latter, we must welcome any means by which scrofula itself can be prevented, or by which, when once initiated, its further development can be checked. According to Albrecht, we can effect the former by inoculation of scrofulous material, conducted in the same way as a vaccination for small-pox. A further means for accomplishing the same end is the refusal to permit a tuberculous mother to nurse her infant, and a limitation, as far as possible, of the marriages of patients affected with syphilis. For the suppression of scrofula when once inaugurated, Albrecht recommends most earnestly the replacement of starchy by nitrogenous diet, and more particularly the employment of peptones as an aliment. Another very useful agent is the inhalation of oxygen. This gas, given to children four or five years of age, in quantities of fifteen to thirty litres twice a day, notably stimulates tissue-metamorphosis, and often renders possible a degree of super-alimentation which could not otherwise be undertaken without endangering the integrity of the organs of digestion.

Miscellany.

The International Medical Congress.—In its last issue the "North Carolina Medical Journal" says:

"Seldom has there been such unanimity of opinion upon any matter

as we have seen expressed in the medical journals of this country on the proposed International Medical Congress. We need not repeat in detail the well-known story of the appointment of the original committee by the American Medical Association, with plenary powers to prepare for the meeting of the Congress in 1887; of the opposition which the printed provisional list of officers and members of the Congress met with; of the movement set on foot to reorganize the original committee, and thus give an opportunity for the admission of some of the malcontents to positions in the Congress; of the reorganization of the officers and councilmen of sections in Chicago in such a way as to distribute the appointments over a larger area of the Union, not failing to 'punish' (as they say in politics) original members who had condemned the New Orleans movement, or were new-code men; how some of the active dissentionists were supplied with prominent places in the new organization; how the leaders of the origiual committee were compelled by self-respect to resign, and the most prominent members of the original body in Baltimore, Philadelphia, and Boston promptly withdrew their names, thus withdrawing from the Congress a considerable number of the ablest men in the country. It is a record painful to make, not only because it means that the Congress can not now possibly be what it could have been under the first organization, but because it shows how large a share of medical politics can enter into the meetings of such a loosely constructed body as the American Medical Association when designing members choose to exert themselves.

"The 'Journal of the American Medical Association' makes the best it can of the situation, but is almost alone in the position it has taken in defending the unfortunate reorganization. We agree with that journal that the new appointments, with a few offensive exceptions, have been judiciously made, but we believe that the whole movement which culmiuated in the Chicago reorganization was discourteous to the original committee, and that the ruling as to the legality of a body having power to reorganize and reinstruct its committees has no bearing upou a purely scientific body, composed of voluntary members, and workiug without any other emolument than the reputation which would ensue from eminent ability brought to the task.

"The sum of the unfortuuate affair may be thus stated: We have been made ridiculous in the eyes of the medical world. The proposed Congress has been severely crippled. The American Medical Association has given evidences of a state of things which must be corrected or be ruined. The new-code men by this blunder have been advanced to a position which no act of theirs could have accomplished for them in a quarter of a century."

The "Maryland Medical Journal," in its issue of August 1st, says: "Despite the very cheering assurances of the 'Jourual of the American Medical Association' that the Ninth International Medical Congress will be conducted in the 'most liberal and enlightened manner' by the 'present able and judicious Committee of Arrangements,' the progress of another week presents a wide-growiug distrust of the recent work of the committee at Chicago. The withdrawal of the appointees of the committee in Philadelphia, Boston, Baltimore, and Washington has been followed by similar resignations in Cincinnati, St. Louis, Chicago, and in other localities. These declinations have come not only from the gentlemen originally appointed by the first committee, but, in a number of instances, the appointees of the present committee respectfully decline to hold the honors awarded to them. Indeed, it seems to be quite appareut that the gifts of this committee will go begging unless some unseen power is raised up to prop its waning fortunes. Under existing circumstances it seems clearly the duty of this committee to abandon its work of reorganization as the most graceful and practical solution of the difficulties which embarrass it. By such a course the committee would in no sense lose the respect of the American profession. It has been placed in a false position by the American Medical Association. It has been called upon to perform a duty which no similar committee of the association can perform under existing circumstances. The present status of the Congress is the result of a false and unnecessary issue which can work no good to the American profession or to the Americau Medical Association. Its introduction into this discussion was totally unwarranted and unjustifiable. The 'code' issue is not an issue which should be raised in the organization of an International Medical Congress. At previous meetings of the Congress all questions of medical politics have been rigidly excluded, and such should have beeu the case in the organization of the present Congress. The gentlemen who have declined to hold positions under the preseut committee of organization are 'old-code' men. Their action has not been influenced by this question. Any attempt to impugn their motives on this ground is an unjust and unwarranted assumption.

"The only point to be considered has been overlooked by the *organ* of the association—in its great devotion to the interests of the present committee of organization—while it vigorously assails the first committee and the gentlemen who decline to serve under the present committee. It is the fact that the Congress is a scientific body, that it is interested only in scientific work, that it should be organized only on a strictly scientific basis, and that the gentlemen intrusted with the conduct of the Congress should be selected out of deference to this fact. The composition of the Congress demanded that men should be selected to its various offices irrespective of geographical position or 'code' politics, but solely on the principle of natural selection—the best men for the best positions.

"We do not deny the fact that the first committee made serious blunders, that the doctrine of natural selection has been overlooked in a number of instances. This fact did not, however, warrant the action of the association in introducing false and absurd issues into the reorganization of the Congress. The first committee performed a difficult duty in a manner perhaps as satisfactory as any similar committee would have done. It considered that it was constituted to organize a body of scientific workers, and it was doing a duty to scientific medicine when it lost sight of geographical lines and medical ethics.

"It is the grossest presumption on the part of the association *journal* to charge these gentlemen with having used the association as a 'decoy duck' to obtain positions for themselves and for their friends, and then 'coolly turn the association into a "foot-ball."' We must regret the illogical and ill-tempered manner in which this 'journal' discusses the points at issue in this controversy. It seems to us its position is poorly taken, and its language is indiscreetly chosen. This 'journal' is now harping on the false issues introduced at New Orleans, and it is no more representing the views of the majority of the members of the association than the few malcontents, who captured the New Orleans meeting, represented the true feelings of the membership of that meeting. Our contemporary is in the position of the ox in the mire. In its efforts to extricate the association from the serious blunders it has made, it becomes more hopelessly entangled. It plunges and charges in the mud of its own make, and hopelessly attempts to fling this mud into the faces of gentlemen who are not responsible for its unfortunate dilemma. It is a trite saying, 'Whom the gods wish to destroy they first make mad.' This seems to be the unfortunate state of mind which besets the leaders of the association and its official *organ* at this time."

The "Canadian Practitioner" says: "We have watched with great interest the progress that has been made in completing the arrangements for the International Medical Congress, which is to be held in Washington in 1887. As our readers well remember, the American Medical Association appointed a committee, giving power to the same to invite the medical world to America, and make the necessary arrangements for the meeting. The invitation which was cordially given was accepted in a very friendly spirit, and the committee proceeded with the work it was asked to perform, and accomplished it most admirably, as we thought. The officers and committees were chosen with great care and prudence, truly representative men being placed in the most important positions.

"We had supposed that the meeting of the American Medical Association recently assembled at New Orleans would gladly indorse the acts of its committee, and say, Well done! go on and complete the work you have so well commenced. But no, says a narrow clique of agitators, you have left certain States unrepresented, you have neglected the rural districts, and, worse than all, you have ignored a number of us bumptious sore-heads, who are superlatively well qualified for the most responsible positions iu the Congress. By some means, a majority of those present were induced to vote for a resolution which prac-

tically censured the committee, and added enough new men to govern the organization for the future.

"The new committee, including some members of the original committee, met at Chicago, June 24th, and made many changes in accordance with the views expressed at New Orleans. Before these changes were confirmed, Dr. Billings explained the situation, from the standpoint of the old committee, as follows:

"'The invitation was purposely worded as coming from the medical profession of the United States, and not from the association only, in order that all regular physicians in the country, and in particular the various important societies devoted to special branches, such as the gynæcological, ophthalmological, laryngological, etc., and also the societies in our large cities which are specially devoted to scientific work, such as the Academy of Medicine, of New York, the College of Physicians, of Philadelphia, etc., should feel that they were included, and must share the responsibility of providing a proper reception for the Congress.'

"This broad view of the question was not acceptable to the committee. They had received orders to decapitate, and they decapitated accordingly. We have neither space nor inclination to discuss at length the merits or demerits of the victims or their substitutes. While, in a general way, we may say that the new appointments should, under ordinary circumstances, be acceptable, this affords no reason why equally good men should be subjected to such humiliation.

"We can not help thinking that the method of procedure was, in all respects, unmanly, ungenerous, and unjust; and we sincerely sympathize with that large portion of the respectable body of the profession in the United States who must feel keenly the humiliating position in which they have been placed. Already this sad business is bearing its bitter fruit. The respectable physicians of grand, conservative old Philadelphia have, in a body, formally declined 'to hold any office whatsoever in connection with said Congress as now proposed to be organized.'

"We had looked forward to a very pleasant and successful meeting at Washington. The ability, generosity, and hospitality of the physicians and surgeons of the United States are well known to the whole world. A few weeks ago the prospects for the proposed Congress were exceedingly bright; now a dark cloud overhangs the undertaking, and what the end will be no one can foresee. We would gladly welcome any solution of the serious difficulties which would bring light out of darkness, but, so far as we can see at present, the prospects are gloomy in the extreme."

The "Independent Practitioner," of New York, one of the ablest of the journals that are devoted to dental surgery, says:

"In the last number of this journal it was announced that the reorganized committee of the American Medical Association had dropped the section of oral and dental surgery from the list of sections established by the original committee. This action demands some notice on the part of dental journals. At the London meeting of 1881 our section played such an important part, it worked in such harmony with the other sections, and contributed so largely to the distinguished success of that Congress, that we had no reason to doubt that, here in America, where dentistry has made such peculiarly rapid strides, where as a branch of medical science it was first organized, where the modern teaching of dentists as scientific men originated—here, among a people who claimed pre-eminence in practical advancement, our specialty would surely be given every opportunity to benefit by this convocation of all that was great in medicine. In London there was no distinction between the various sections. In free democratic America it was anticipated that a section that would probably number more delegates than any other would be given peculiar facilities. We are happy to say that the Congress, as first organized by representative medical men, had fulfilled all expectations. It remained for a rump association to outrage respectable medicine by overturning that which had been established, and to attempt to found a World's Congress upon sectional issues. It shows a woful misconception of the character and purposes of the Congress when local quarrels and questions of personal bias are injected into the discussion thus early. They must indeed be men of narrow views who would force a world's professional assembly to take sides on a division of opinion among the physicians of the State of New York. Will medicine as a whole never get above these petty squabbles? Will it never make good its boast of being a learned profession, and rise superior to the pot-house wrangles which engage only minds of small caliber?

"That dentists may understand the present status, it is necessary that we explain some things that may not be known to all of them. The International Medical Congress is what its name indicates—a council of the representative medical men of the world, which meets every third year. It knows nothing of medical societies or medical politics, but at each meeting accepts the invitation of the medical profession of some country to hold its next session with them. It is never the guest of any medical society, but it expects that the whole profession of the country in which it meets will join in advancing its interests. It is not intended to be a convocation of small men, nor is it anticipated that it shall be so used as to advance individual interests. Especially does it discourage all professional demagogism. In this country the American Medical Association, as the nearest approach to a national organization that we have, assumed to issue the invitations through a committee of representative men, who, in the event of its acceptance, were directed to complete an organization. This committee visited Copenhagen, where the Congress of 1884 was held, extended the invitation, which was accepted, and the committee thereby became an organizing committee of the Congress.

"They returned home and proceeded to complete their work by adopting rules, establishing sections, and appointing their officers. That this work was well done there can be no question. But upon the reassembling of the American Medical Association in New Orleans, in March last, in a place remote from the great medical centers, and where the membership for the year would necessarily be made up largely of those who were not conversant with the needs and feeling of the profession, it was found that a few determined demagogues, oily of tongue and reckless of the best interests of the profession, had secured control of the association. They did not belong to the class of men who have made medicine what it is. They were in no sense representatives of the better part of medical science, and so they had not been appointed to commanding positions. But they were determined in some way to make the Congress personally profitable to themselves, and they accordingly headed a movement which resulted in the undoing of all that had been done, and the appointment of a practically new committee, with themselves in the prominent positions.

"The plea under which this was done was, that the organization of the Congress did not properly represent the country, and that some of the new-code men of the State of New York had been appointed to office. The speciousness of this claim will be seen when it is understood that this is not a political assembly; it is not the *country* which is to be represented, but the profession of medicine, and such men should be chosen as best typify the great profession, no matter if they were all found in one city. If the backwoods of Arkansas could furnish a man who could take rank with the leading minds of medicine, he should be chosen. But, if not, Arkansas should wait until it could produce such a man. As to the factional issue of new or old codes, that was a matter with which the Congress had, and desired to have, nothing whatever to do.

"But the new committee assumed the reins, and proceeded to reorganize the Congress, displacing some of the men whose fame is world-wide, and who cast a luster upon medical science, and putting in their places some of the ambitious 'outs' who were great only in their own conceit. They reduced the number of sections, dropping that of dental and oral surgery, or, what is the same thing, consolidating it with general surgery. The 'Medical Bulletin,' of Philadelphia, which is edited by one of the leading spirits in the revolution, says: 'The omission of the section of dental and oral surgery was judicious, dentistry not being generally recognized as a legitimate department of medicine.' We may well be content to rest under his ban, when he is at known issue with very much that is reputable and honorable in medicine.

"Anticipating censure, the new committee fortified themselves with the opinion of lawyers concerning the legality of their action. To what end? What have lawyers to do with the ethics of another profession? Did the committee propose to go to extreme legal limits, or was it their desire to do what was professional and right?

"As might he imagined, their proceedings have excited a deep and indignant feeling among the better part of physicians. The protests have been many and vigorous. The most of the leading medical journals have forcibly denounced the movement. Meetings of leading medical men have been held in several of the large cities, and many of the most respectable of the appointees have announced that they will have nothing to do with the Congress as now organized. In Philadelphia, such men as Agnew, Bartholow, Brinton, Da Costa, Gross, Hays, Leidy, Mitchell, Stillé, Tyson, Wood, and many others, with Yandell, of Louisville, have formally withdrawn. The Philadelphia list of protestants alone includes four presidents of sections.

"This action has been imitated in other cities, and so many eminent names have been withdrawn that it now seems demonstrated that, under the present organization, the Congress can not by any possibility be made a success. The men now charged with the management of the Congress are believed to be incompetent, and they certainly do not possess the confidence of the profession, nor are they sufficiently representative of the intelligence of those for whom they assume to act. Therefore, as we said in the last number, it is probably as well that we are not involved in the quarrel. The only thing that remains is to see if the Congress can not be rescued from the hands of those who have assumed its management. But even this could not probably be done in time to re-reorganize with much hopes of making it what it should have been.

"It is a shame and a scandal to medicine that such a state of affairs can exist. But as long as such an organization as the American Medical Association, with its fluctuating, constantly changing membership, shall be the representative Association of American Medicine, we have little better to hope for. It is a complete political body, and, like all such associations, it is usually controlled by demagogues and wire-pullers. What medicine needs is a permanent body, that shall represent, not its tricksters and politicians, but its intelligence, its professional eminence, and its scientific attainments. This the American Association does not and can not do, because its membership is founded upon geographical, and not upon scientific or professional representation. It now seeks to make the International Medical Congress but an enlarged session of this unrepresentative body."

In the course of a spicy article entitled "The Late Proposed Medical Congress," the "Peoria Medical Monthly" says:

"The Philadelphia protest and withdrawal contained twenty-eight names, that from Boston nineteen, and Baltimore twelve, with more to hear from. Twenty-seven from New York were ignominiously hounced, and the list of officers and committees as it now stands is bereft of such names as Loomis, Emmet, Bulkley, Keyes, Lefferts, Mundé, Knapp, Bosworth, Packard, Da Costa, Bartholow, Pepper, Mitchell, Gross, Hays, Agnew, Parvin, Goodell, Leidy, Stillé, Yandell, Williams, Blake, Chadwick, Chisolm, Johnston, Mackenzie, Lee, Tiffany, Theobald, Johnson, Burnett, Prentiss, Baker, Huntington, Engelmann, etc.

"Poor Congress! it looks as if it had 'died abornin',' or, at least, was having an awful hard time to get started into this world (western part of it) of sorrow and contention. The office of secretary-general is vacant. The sections of therapeutics, medicine, anatomy, and surgery are without heads, and other sections are partially dismantled. And still the fight goes on."

The "New Orleans Medical and Surgical Journal" says:

"So, at the New Orleans meeting of the American Medical Association, the report of the committee was presented and disapproved. Many of our readers will recall the intemperate discussion on the occasion. It was characterized by offensive personalities, well calculated to widen the differences already existing. One spokesman from the West, in imitation of the wicked ruler who leveled the highest reeds in his garden as a warning to his subjects, proposed to behead the great men of the East. The sentiment was applauded. As a crowning act of discourtesy to the original committee, composed of some of the most honored names on the roll of the association, a resolution was finally adopted appointing a new committee, to be composed of the membership of the original committee of seven, enlarged by the addition of thirty-four members of the association, one from each State and Territory represented, and from the Army, Navy, Marine-Hospital Service, and the District of Columbia. To the new committee, thus constituted, was granted the power of reviewing, altering, and amending the work of the original committee, as deemed necessary. This enlarged revisory committee some of our most esteemed contemporaries choose to call the 'New Orleans Committee.' True, the committee was born here, but of foreign parentage, and certainly conceived elsewhere. It is a fact worthy of record that not a single Louisianian raised his voice in the discussion which led to the organization of the new committee.

. . . . . .

"Already it is painfully evident that it is simply impossible to organize the American meeting of the International Medical Congress upon the plan adopted by the Chicago committee. Truly, we stand to-day a divided household, and, unless some reconciliation can be effected, the failure of the Congress is inevitable. The present situation is deplorable beyond expression. A mighty responsibility rests on the present Committee on Organization. The members must realize the impossibility of organizing the Congress in further pursuance of the policy recently adopted. For the sake of harmony, through which alone the Congress can succeed, and the profession escape a national disgrace, the committee should make concessions to the gentlemen who feel aggrieved by their action; and such concessions to those who have resigned, as well as those who have been displaced, should meet only friendly responses and pledges of harmonious co-operation.

"We favor the organization of a National Committee of peace-makers, composed of representatives from the States and Territories, to be appointed by the presidents of State and Territorial societies; from the District of Columbia, to be appointed by the president of the District Society; and from the Army, Navy, and Marine-Hospital Service, to be appointed by the ranking medical officer of each service."

The "Canada Lancet" says:

"This action on the part of the leading members of the profession seems a most serious step, but it arises from the fact that there is a growing want of confidence in the ability of the American Medical Association, as an organization, to carry out such an undertaking satisfactorily, and also in the probable success of any Congress from which the best known scientific men of the country are excluded. The action of the committee in regard to the 'new-code' men would indeed be ludicrous were it not so serious, and will have the effect of creating sympathy where before there was only cold and formal respect. The insult offered to such veterans as Bowditch, Fordyce Barker, Draper, Weir, Mundé, Roosa, Knapp, Noyes, Agnew, Jacobi, and others, merely because of a difference of opinion on the code question, will not be tolerated by the good sense of the American medical profession."

The "British Medical Journal" says:

"The most recent advices from the United States have brought the startling intelligence that there exists in the American medical profession a very serious discord concerning the next International Medical Congress. We do not propose to discuss the ætiology of this rupture, for it is quite enough to be called upon to face the fact that it exists. The fact is very grave. Its existence jeopardizes, if it have not already destroyed, the probable success of the forthcoming Congress. Certainly our brethren in the States can not expect those who have already promised to attend, and those who may expect to visit America at that time, to work with enthusiasm in the preparation of any scientific contributions while those whom they propose to visit are divided, and while wholesale secessions of the official executive and of well-known persons nominated to high offices are announced. Nor do we consider it to be either our duty or privilege to suggest a remedy for this exceedingly unpleasant dilemma. It seems to be conclusive that the profession in America at this moment is hopelessly divided on the subject. Already a large proportion of the influential and active scientific men of Philadelphia—such as Bartholow, Weir Mitchell, Da Costa, H. C. Wood, Pepper, Leidy, Stillé, Parvin, and Goodell, and David Yandell, of St. Louis—have publicly withdrawn from the organization of the Congress. A like number of distinguished men in New York—such as Loomis, Roosa, Jacobi, Mundé, Agnew, and Emmet—have also either resigned or been dropped, and therefore will not co-operate with the present organization. The outlook as the matter now stands is not at all encouraging. One committee has reorganized the work of another up to the point near that of destruction. Moreover, the work of the present

committee must be submitted to the American Medical Association in May, 1886; and no one can say to what extent it may also be either overturned or modified in such a way as to seriously impede the labor necessary to be performed before the meeting of the Congress in 1887. Altogether, the position is lamentable, and there is much fear that the acceptance of the invitation to meet in the States may be withdrawn, and the next meeting of the International Medical Congress be held in Berlin, or some other great medical center, pending the settlement of the serious dissensions among our brethren of the United States."

Clinical Teaching in Obstetrics and Gynæcology.—It is pleasant to note the constant increase of the facilities for the practical teaching of these branches in New York. Besides the professors and instructors at the Polyclinic and the Post-Graduate School, there are now several very capable private instructors holding clinical appointments. We would call attention to Dr. Garrigues's card, which appears in our advertising columns this week, and assure our readers that he will be found most efficient as a teacher of obstetrics and gynæcology.

The University of Charkow.—The "St. Petersburger medicinische Wochenschrift" states that Dr. J. Lasarewitsch, having served the appointed time as professor of obstetrics and gynæcology, has been made a professor emeritus.

The University of Berlin.—We learn from the same journal that Professor Gerhardt, of Greifswald, has been called to Berlin as an ordinary professor in the medical faculty, and to succeed Professor Leyden in the service at the Charité.

The Death of Professor Vogt, of Greifswald.—The same journal announces that Dr. Paul Vogt, the Greifswald professor of surgery, died suddenly, of heart disease, on the 5th of July, in the forty-second year of his age. He had held the full professorship for only three years, having succeeded Hüter in 1882.

THERAPEUTICAL NOTES.

The Summer Diarrhœas of Infants.— The "Medical Age," of Detroit, contains, in its issue for July 25th, a valuable article on this subject, by its editor, Dr. J. J. Mulheron. He treats first of the causes of these affections, dividing them into simple diarrhœa, eutero-colitis, and cholera infantum, and then speaks of the treatment as follows:

"The first thing necessary in undertaking the treatment of a case of 'summer complaiut' is to decide to which of the three forms of intestinal disturbance above referred to the case belongs, and, having settled this point, to settle on some definite theory of its nature and the pathological conditions which obtain. Without these preliminaries the physician must flounder aimlessly about.

"The armamentarium which I would suggest in going out to cope with the summer diarrhœas of infants comprises the following drugs and remedies, it being understood, of course, that the dietary shall be determined *pro re nata*. The drugs are mentioned at random, and are not given in the order of their importance: Castor-oil, prepared chalk, calomel, creasote, salicylic acid, opium, strychnine, vegetable astringents, ergot, belladonna, chamomile, bromide of potassium, sulphuric acid, subnitrate of bismuth, oxide of zinc, cocaine, the spice poultice, and warm and cold baths.

"A brief review of the physiological action of these may assist to their therapeutic application. Castor-oil is a mild but decided purgative, and is at the same time an emollient through its action on the intestinal mucous membrane. Prepared chalk (carbonate of calcium) is an antacid. The belief that calomel is a cholagogue is now very generally discarded. The drug has, doubtless, a complex action, but for our present purpose it is sufficieut to state that it is an antiseptic, having specially marked anti-fermentative properties. Experiments conducted by Wassilief in Hoppe-Seyler's laboratory are quite conclusive as to its influence in preventing decomposition and butyric-acid fermentation in the intestines. Added to a cultivating fluid, it prevents the development of micro-organisms, while it destroys the activity of those which have already formed. These properties are, probably, due to the formation of the bichloride of mercury through its union with the chlorides of the stomach. Creasote is intensely poisonous to all forms of infusoria and fungi. It allays irritative conditions of the gastric nerves and becomes thus also an excellent anti-emetic. Salicylic acid destroys low forms of organic life and ferments. Opium has a very manifold action, but for our present purpose it is sufficient to recall the fact that it is an anodyne, that it diminishes peristaltic action of the bowels, and that it checks secretion from all surfaces except that of the skin. Strychnine, besides its characteristic action on the spinal motor nerve-centers, influences also such portions of the cord as affect the vaso-motor centers. Without being able to state its exact physiological action in this direction, clinical experience has demonstrated its value as a tonic in atony and relaxation, both of striated and non-striated muscular tissue.

. . . . . .

"Ergot has the peculiar property of causing vaso-motor spasm, and its action is noticeable in the non-striated muscular fiber of the intestines as in the same tissue found elsewhere. Belladonna is a stimulant to the vaso-motor centers, causing contraction of the capillaries. It checks secretion from glands. It relieves pain, Anstie regarding it as the best remedy to mitigate pain of every kind in the pelvic viscera. Chamomile, through the volatile oil which it contains, possesses the power of subduing reflex excitability. Grisan found it impossible to tetanize with strychnine a frog which had been fortified with chamomile, and, *vice versa*, when excitability had been produced by strychnine it could be calmed by means of chamomile oil. The power of bromide of potassium in allaying reflex excitability is well known. Subnitrate of bismuth acts, probably, locally, forming a coating over the mucous membrane and protecting it from the action of irritants. Oxide of zinc, besides being an astringent, possesses also the property of allaying reflex irritation. Sulphuric acid is tonic and astringent, with an apparently specific action on the intestines. The local anæsthetic action of cocaine has been so much discussed recently as to make reference to it unnecessary. It suggests itself as an application to the irritated gums. The spice poultice is a counter-irritant, and is, probably, also antispasmodic through absorption of the oils which it contains.

. . . . . .

"*Simple Diarrhœa.*—Assist the effort of nature to rid the bowel of irritant matter with a dose of castor-oil. Follow this by sufficient doses of prepared chalk to correct the acidity of the discharges, give opium to diminish the peristaltic action, and give astringents and strychnine to restore tonicity. The following is a good formula for a child of, say, eighteen months:

Tr. opii camph.	℥ ss.;
Ext. rubus villos. fl.	℥ j;
Tr. nucis vomicæ.	gtt. xij;
Mist. cretæ.	q. s. ad ℥ iij.

M. Sig. A teaspoonful every three hours.

"*Entero-Colitis.*—When the character of the stools, the elevation of the temperature, the disturbance of the stomach, etc., indicate the involvement of the intestine in a catarrhal inflammation, the means employed in the simple diarrhœa, which is usually the precursor of these graver symptoms, must be supplemented by other remedies. Place the child on small doses of calomel and ipecac—say a twelfth of a grain of each for a child of eighteen months—every two hours, alternated with a teaspoonful of an infusion of five chamomile flowers in a cup of boiling water. The spice poultice, moistened with hot brandy, must be laid over the abdomen. If the temperature pass 101° F., it must be reduced by baths, the water of which must at first be tepid, and gradually cooled to 70° F., or lower, as the circumstances of the case require. Should twenty-four or thirty-six hours of this treatment be followed by no betterment, and the stools continuing or becoming more colliquative, I have found the following formula to answer admirably, quieting the irritability of both the stomach and the bowels:

Creasoti.	gtt. iv;
Zinci oxidi.	gr. xvj;
Tr. belladonnæ	ʒ ss.:
Glycerini.	℥ ss.;
Aquam.	q. s. ad ℥ ij.

M. For a child a year old: Sig. A teaspoonful every three hours. This may be alternated with aromatic sulphuric acid, two drops in ten drops of brandy, every three hours. The spice poultice should be continued.

"*Cholera Infantum.*—Bearing in mind our conception of this affection as a neurosis, our treatment should be directed, 'first, to destroying the organisms, on which every fermentation depends for its development; secondly, to allaying the irritation of the end organs of the splanchnics in the mucous membrane; thirdly, to arresting the outward osmosis from the vessels; fourthly, to lowering the febrile temperature and removing the algid condition.' My experience leads me to speak with favor of salicylic acid and chalk, as recommended by Dr. Hutchins in the September, 1880, number of the 'Proceedings of the Medical Society of the County of Kings,' N. Y., as a remedy meeting the first and second of these indications. This combination is useful only in cases of serous diarrhœa, having no efficacy in the inflammatory or lienterie form. It acts happily, also, in allaying gastric irritability. Three grains of salicylic acid, rubbed up with two grains of prepared chalk, should be given every three hours. Care should be taken that the chalk be pure, and that, during the effervescence attending the addition of water to the powder, no odor of chlorine be emitted. Such odor denotes the presence of chlorine—a residuum of the manufacture of chlorinated soda. It is apt to exist in prepared chalk, and should be carefully avoided. The creasote formula, given above, for entero-colitis, has also answered a good purpose, especially in cases attended with much gastric irritability.

"There are few cases of cholera infantum in which the bromide of potassium will not prove helpful, and especially when there exist restlessness, wakefulness, and twitching of the muscles. It allays the irritation of the splanchnics, and of the nervous system generally.

"Baths hold an important place in the treatment of the fever of cholera infantum, and for one reason, among others, that it is of little use to administer medicines as long as the temperature is elevated. The soothing influence of a cold bath on a child whose temperature has reached, say, 103° F., and the increased activity of the drugs administered after the bath, need but to be witnessed to make converts to this much neglected remedy in the treatment of cholera infantum. The child should be immersed up to its neck in water at a temperature of 95° F., to which cold water should be added until the bath reaches 70°, or even lower, the condition of the patient, his temperature, etc., being the guide to the reduction. No hard-and-fast rules can be laid down to govern the temperature of the bath or its frequency. The condition of the infant must be the guide, which the good sense of the physician must be trusted to interpret and follow.

"When the child has entered the algid stage of the disease, treatment offers little hope of rescue. Alcoholic stimulants and warm baths are about the best we can apply. Belladonna, through its action on the heart, suggests itself as a remedy in this condition, and experience has shown it to be of value. By paralyzing the terminal inhibitory filaments of the pneumogastric, it gives the heart over to the sympathetic, and we have, as a consequence, increased rapidity of contraction and raised arterial tension—a condition of affairs which it would seem very desirable to secure in the cold stage."

Osmic Acid in the Treatment of Neuralgia.—Schapiro ("St. Petersb. med. Woch.") summarizes the results met with by a number of observers in the use of injections of osmic acid for the relief of various forms of neuralgia, and gives the details of his own experience, which relates to eight cases: 1. A woman, thirty-eight years old, was cured of a neuralgia of the second and third branches of the right trigeminus by twelve injections. 2. A woman, fifty-two years old, was cured of a neuralgia of the same branches by twenty injections. 3. A woman, thirty-eight years old, with neuralgia of the first and second branches of the left trigeminus, was improved by ten injections. 4. A woman, thirty-six years old, was cured of a neuralgia of the second and third branches of the right trigeminus by one injection. 5. In the case of a woman, thirty-three years old, with neuralgia of the occipital nerve and both trigemini, one injection seemed to increase the severity of a moderate paroxysm, and she declined the further use of the remedy. 6. A man, sixty years old, with neuralgia of the second and third branches, of the right trigeminus, was improved by twelve injections. 7. A man sixty years old, was cured of a neuralgia of the first and third branches of the right trigeminus by eight injections. 8. A man, fifty-three years old, was cured of a neuralgia of the second and third branches of the right trigeminus by six injections. Momentary faintness followed an injection in one instance, but he states that, with that exception, he has observed no unfavorable effects.

The Use of Ergot during Labor.—Säxinger, of Tübingen ("Dtsch. med. Wchnschr."; "Ctrlbl. f. Gyn."), defends the use of ergot during the expulsive stage of labor, provided the head is low in the pelvis, and even in cases of contracted pelvis, after the head has become fully molded. He quotes Schatz to the effect that ordinary doses simply increase the frequency of the uterine contractions, without making the individual pains stronger. At Scyfert's clinic, for the past three years, he has observed excellent results from the use of an extract recommended by Dr. Denzel, which is said to contain none of the active principles but sclerotinic acid, ergotin, and ecboline. Rather more than a grain and a half of this extract may be considered the equivalent of fifteen grains of powdered ergot. The author thinks that the use of ergot during labor will be recognized as legitimate so soon as a preparation free from deleterious constituents becomes generally available.

Salicylic Acid in the Treatment of Chancroid.—Notta ("Union méd.") gives the following formulæ:

Salicylic acid		1 part;
Flour, Powdered gum arabic,	each	2 parts.

Mix.

Salicylic acid		3 parts;
Oxide of zinc, Powdered starch,	each	15 "
Vaseline		20 "

This ointment is used by Mauriac at the Hôpital du Midi.

The Treatment of Pyrosis.—A contributor to the same journal gives the following formula, on the authority of Peter:

Powdered bicarbonate of sodium		37 grains;
Prepared chalk		15 "
Extract of nux vomica		1½ grain.

Mix and divide into ten powders, one to be taken three times a day. They are prescribed for persons with whom a milk diet disagrees, but for whom that diet is ordered. If diarrhœa occurs, subnitrate of bismuth is given, in doses of seven or eight grains, with a sixth of a grain of extract of nux vomica, and from a sixth to a third of a grain of powdered opium.

The Treatment of Whooping-cough.—The same writer (*Ibid.*) attributes to Roger the following method of treating prolonged and severe whooping-cough ("*hypercoqueluche chronique*"):

Ammoniac		1½ to 7½ grains;
Syrup of orange-flowers or of red poppy.		375 "
Infusion of elecampane or of Virginia snakeroot		1,125 "

Dose, a teaspoonful, to be repeated with greater or lesser frequency, according to the child's age and the effect produced. When the expectoration is very abundant and as if formed of muco-pus, a terebinthinate (syrup of fir-cones, of eucalyptus, or of turpentine) is prescribed. Flowers of sulphur, mixed with honey (from three quarters of a grain to two grains or more of sulphur), may also be given twice a day. It is well, too, to rub the chest or the sides of the neck with a soothing ointment, such as one containing a drachm of the extract of aconite or of conium to half an ounce of lard.

Menthol as a Local Anæsthetic.—Rosenberg ("Berl. klin. Wchnschr."; "Lancet") finds that a twenty- or thirty-per-cent. solution of menthol, which is much cheaper than cocaine, is a useful substitute for the latter as an anæsthetic application to mucous surfaces, like those of the nose, the pharynx, and the larynx. Although its effect is more evanescent than that of cocaine, it appears to be somewhat cumulative, for, when repeated, even after a long interval, the later application produced a longer period of anæsthesia than the earlier one.

Original Communications.

OBSERVATIONS ON THE MEDICAL AND SURGICAL TREATMENT OF ACUTE PERITONITIS.*

BY T. HERRING BURCHARD, A. M., M. D.,

LECTURER ON SURGICAL EMERGENCIES, BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON, CHARITY HOSPITAL, ETC.

PERITONITIS may well be regarded as the most fatal of the acute inflammatory diseases. After a careful compilation of various hospital statistics, etc., I think its mortality may be set down, when all varieties of the disease are considered, at about from fifty to sixty per cent., and from twenty to thirty per cent. higher when so-called "idiopathic cases" are excluded. Indeed, as is well known, there are certain cases, especially such as are incident to septic poisoning, and others that follow perforation of the bowel, in which a fatal termination may be said to be inevitable.

Believing that this mortality is unnecessarily high, and that certain patients with peritonitis are permitted to die who, perchance, under different procedures might be saved, it is my desire to formulate and emphasize certain principles of treatment already known, although not as yet generally accepted by the profession.

All treatment, to rise above mere empiricism, must rest upon a threefold conception—a conception of the cause of the disease, a conception of the natural history of the disease, and, finally, the natural tendencies of the disease, or a foreknowledge of the mode of recovery or death. These principles apply with special pertinency to the treatment of peritonitis, and, before we can expect to treat that disease rationally, we must first know what causes it, and then how it kills.

Without going into unnecessary detail, it will suffice to know that peritonitis may originate from *external traumatisms*, from *internal traumatisms*, by extension of inflammation from contiguous parts, from septic causes and certain blood diseases (as rheumatism, Bright's disease, etc.), and possibly, though rarely, from causes that are purely miasmatic and climatic, constituting the so-called idiopathic cases.

Now, what are the causes of death?

According to the text-books, collapse and asthenia. According to clinical and pathological observation:

1. *Collapse*, which represents the shock received by the nervous system from injury inflicted on the largest serous membrane of the body.

2. *Asthenia*, which may be more intelligently expressed by, *a*, heart failure; *b*, respiratory failure.

3. By inflammatory changes in the lungs.

4. By inflammatory changes in the kidneys.

5. By *hyperpyrexia* as a special cause, superinducing any or all of the foregoing.

Any treatment, to be successful, must be prosecuted in the light of these clinical facts, and, in this understanding, the following considerations are submitted:

1. The rarity of idiopathic peritonitis being now generally admitted, it is of paramount importance that each case should have its ætiology definitely determined at as early a period as possible.

The mere fact that peritonitis exists is not sufficient in itself to justify the adoption of any course of treatment. This primary diagnosis, like the sign-board by the wayside, simply points the way to further explorations.

So long as peritonitis is regarded as a finality rather than as the expression or symptom of some organic disturbance, but little help can be expected from other than a purely empiric line of treatment.

The views of the profession have undergone a great change in this respect. As Dr. Savage tersely puts it ("Brit. Med. Jour.," January 31, 1885), "We are learning, if we have not already learned, to look on peritonitis as a symptom of some organic change, and not as a disease in itself. And this is well for our patients, because operative measures can do much for it. We shall, ere long, regard so-called 'idiopathic peritonitis' almost as a curiosity."

In no other disease is an early knowledge of the causation of the attack so essential, and yet how often is the ætiological factor totally ignored in our haste to adopt a course of treatment which, while it mitigates symptoms and apparently gives relief, at the same time unwarily leads us on to a fatal though, perchance, a painless finale!

It is in the incipiency of the attack, before excessive tympanites has disturbed the normal configurations of the abdomen and fatal asthenia has developed, that the golden opportunity for successful diagnosis exists.

One word as to the alleged difficulties of accurate diagnosis under such circumstances. So much has been said on this subject that they have come to be regarded as well-nigh insuperable. Yet, under a systematically conducted examination, which necessitates the interrogation of each abdominal viscus and which seeks to find a satisfactory explanation for each abnormal symptom, it is surprising how the difficulties will dissipate. It is owing to a want of thoroughness in the examination and a lack of the judicial element in weighing symptoms, rather than to inherent difficulties often, that the diagnosis seems so obscure. Six times have we seen fatal peritonitis develop after acute perforation of the vermiform appendix, and in five cases out of the six has the autopsy verified the diagnosis. ("N. Y. Med. Jour.," January, 1881.)

Of nine cases of *intestinal obstruction* that have fallen under our personal observation, two cases have recovered without surgical interference; hence the diagnosis could not be verified. Of the remaining seven, a positive diagnosis was made in five. In three of these I did laparotomy—twice with success. The autopsy revealed the correctness of diagnosis in the two remaining cases. (See "Transactions of N. Y. Co. Med. Soc.," meeting of April 7, 1884, p. 296.)

These diagnoses were made and the local lesion differentiated under conditions of collapse, tympanitic distension,

* Read before the New York Academy of Medicine, May 21, 1885.

and abdominal pain, for these are the prominent symptoms ushering in acute peritonitis, and are cited in this connection to show that a diagnosis which is practically accurate is feasible. (For fuller information regarding diagnosis the reader is referred to an article by the author on "Operative Interference in Acute Perforative Typhlitis," "N. Y. Med. Jour.," January, 1881.)

2. The diagnosis being made, and a local lesion amenable to surgical interference being demonstrated, surgical relief should be rendered at the earliest moment practicable.

The peritonæum behaves very differently under different circumstances. It seems scarcely credible that the same structure that will passively submit to the enormous distension of a gravid uterus or an ovarian cyst would reject so summarily the trifling local irritation consequent upon some minute intestinal perforation. Yet such is its behavior under acute irritations that the rule might well be formulated that all foreign substances, solid, liquid, or gaseous, of an irritating nature, when introduced into the peritoneal cavity, will inevitably and rapidly produce acute inflammation. The history of such traumatisms is, as we have shown, most unfortunate, the terrible features of the attack precipitating themselves with a rapidity and malevolence that are simply appalling.

What, under the circumstances, are the indications for treatment? Were the irritation located elsewhere in the body than in this much-dreaded locality, sound surgical judgment would advise the immediate removal of the irritant. Why, then, should the peritonæum, a structure which is daily proving its immunity to surgical manipulation by giving to surgery its brightest triumphs, not be subjected to the same wise principles that guide us elsewhere in our operative procedures?

True, it is no trifling responsibility we assume when we propose, in the very face of a commencing peritonitis, to open the cavity of the abdomen, release a strangulated bowel, divide constricting bands, or cleanse the cavity from purulent extravasations. But, in view of the exigencies of the situation and the absolute imminence of death, do we shift these responsibilities one iota when we sit supinely by, knowing full well the inevitable fatality that attends the orthodox methods of treatment? What ovariotomist is there that would hesitate a moment to remove stitches and reopen a wound in case internal bleeding or purulent accumulations demanded it? Too well does he know the fatality of temporizing. How many more valuable lives, then, are yet to be sacrificed before the profession realizes the necessity of surgical interference in these desperate cases of internal abdominal traumatism?

Marion Sims ("Brit. Med. Jour.," December 17, 1881) in this very hall sounded the key-note of the future treatment of such cases when he said: "Given a case of perforation of intestine, and given an accurate diagnosis, which is by no means difficult, what are we to do in the present state of our knowledge? Why, of course, we should open the abdomen promptly, clean out the peritoneal cavity, search for the perforation, pare its edges and bring them together with sutures, and treat the case as we now treat other cases involving the peritonæum. Rest assured," he says, "that the day will come, and it is not far off, when an accurate diagnosis in such cases, followed by prompt action, will save life that must otherwise quickly ebb away."

Dr. Robert W. Johnson, chairman of the Surgical Section of the Medical and Chirurgical Faculty of Maryland, said in his Annual Report (N. Y. "Med. Record," p. 550): "The greatest triumphs of the year (1884) are in abdominal surgery, Dr. Bull's case of laparotomy and suture of the intestine for gunshot wound being the greatest of them all." He then goes on to state: "The abdomen should be opened in case of perforation of intestine, hæmorrhage, extravasation of fæces, and *beginning peritonitis*, just as in cases where internal strangulation has been positively diagnosticated, but only under full and complete Listerism, (1) because without operation the patient is almost sure to die; (2) the danger is far more than counterbalanced by the chances of recovery."

To familiarize myself with the technique of the operation, three times I have laparotomized dogs, resected one or more segments of intestine, suturing with catgut the divided gut, and, notwithstanding the difficulty of keeping the animals quiet, they all recovered. Twice I have subcutaneously perforated with a slender bistoury the gut of a dog, and, after forcibly squeezing some of the intestinal contents and blood into the peritoneal cavity, have opened the animals, washed out the abdomen, sutured the perforations, and had one of the dogs recover.

The point raised by Dr. James R. Wood in the discussion on Dr. Sims's paper, to which reference has already been made—namely, that "pathological surgery or operations done for tumors and disease were very different in their results from traumatic or acute surgery, and that this was specially true regarding manipulations of a large serous membrane that resents all impertinent interference"—does not, it seems to me, afford a sufficiently logical basis for doing or not doing the operation.

As a clinical fact, the peritonæum is exceedingly tolerant of interference, provided the proper precautions are observed.

Note the vast number of Tait's operations alone that have been done during the last three years, and the splendid results that have been obtained. Death in these cases has resulted from peritonitis but rarely. More frequently it has been from septicæmia or shock.

In order to show the tolerance of the peritonæum under operations done for the relief of acute irritations, as well as to emphasize the principle I maintain, I beg to present in evidence the following cases, purposely omitting all cases of hernia or intestinal obstruction, referring the reader to Mr. Treves's recent excellent work on the latter subject:

Case I. Kuester ("Verh. d. deutsch. Gesellsch. für Chirurg.," viii, 1879).—Rupture of the sac of an incarcerated crural hernia with escape of fæces into the peritoneal cavity during a kelotomy. Immediate laparotomy and resection of the gut. Death from septic peritonitis.

Case II. Scheide ("Verh. d. deutsch. Gesellsch. für Chirurg.," 1878).—Laparotomy in a case of incarcerated umbilical hernia with gangrene of the gut.

Death four days after operation.

Case III. Schetelig ("Berl. kl. Wochenschr.," xvii, 80, 607).—Knife wound of the abdominal wall in a decrepit man of sixty. Protrusion and laceration of a part of the colon. Reposition impossible at first. Enlargement of the upper part of the wound with subsequent replacement of the bowel. Recovery.

Case IV. Wittelshoefer ("Wien. med. Wochenschr.," xxxi, 81, 118).—Man brought to Bamberger's clinic with the following history: Some days before he had introduced a painter's brush into the rectum to stop a diarrhœa, but when he tried to take it out it had disappeared. On admittance, presents signs of peritonitis, and examination shows the presence of the body in the sigmoid flexure. Other means proving of no avail, he is transferred, three days after, to Billroth's clinic for operation. Patient at this time gives symptoms of severe peritonitis and is somewhat collapsed.

Operation by Billroth.—*Laparotomy.* Incision beginning at anterior superior iliac spine and extending as far as the symphysis. Peritoneal cavity is found filled with fæcal matter, indicative of a perforation. Brush found in the ascending colon and removed by an incision 7 ctm. in length.

Toilet of peritonæum, wound of gut sutured, severe collapse after operation. Death.

Autopsy shows perforation of the peritoneal covering of the gut 25 ctm. above the anus.

Case V. Wittelshoefer ("Wien. med. Wochenschr.," 1881, xxi, 118).—Man, aged fifty-two, brought to Bamberger's clinic, November 8th, with obstinate constipation of six days' duration. On admittance, presents already signs of peritonitis, stercoraceous vomiting, etc. He is found to have a small umbilical hernia, reducible.

Transferred to Billroth's clinic November 18th. At that time already in collapse. The hernia is not so easily reduced, and is somewhat painful.

Laparotomy. Incision in linea alba 18 ctm. in length. On opening the peritoneal cavity, a quantity of fœtid matter oozes out, and there are signs of a general peritonitis. Examination shows gangrene of the gut a little above the ileo-cæcal junction, and volvulus. Resection. Death in collapse five hours after operation.

Case VI. Assmuth ("St. Petersb. med. Wochenschr.," 1881, vi, 118).—Incarcerated umbilical hernia in a man aged forty-five. Symptoms of acute ileus.

Laparotomy. Omentum and gut found gangrenous and excised. Sutured. Recovery.

Case VII. Weinlechner ("Jahrb. für Kinderh.," 1881, xvii, 304).—Laparotomy in a child five years old, with intussusception after the development of acute purulent peritonitis. Resection of intussuscepted part.

Death five hours after operation from exhaustion.

Case VIII. Hoffmann ("Wien. med. Presse," 1881, xxii, 114).—Man aged twenty-four brought to Bamberger with acute gastric symptoms. Diagnosis: perforating gastric ulcer. Transferred to Billroth. Laparotomy performed and shows a perforating ulcer on upper curvature. Edges are excised and united by sutures. Death day after operation.

Autopsy shows an enormously distended stomach with thickened walls. What had been taken for an ulcer was probably a spontaneous rupture, the result of the extreme distension.

Case IX.—Hagens ("Berlin. kl. Woch.," 1883, xx, 106).—Historical account of one of the oldest cases of gastrotomy, 1635.

Operation performed by Schwab on a peasant who had swallowed a knife. Incision two fingers' breadth under the free border of the ribs. Wound in stomach united by sutures; abdominal wound closed. Recovery.

Case X. Maurer.—Perityphlitis in a man aged seventeen. Incision extending from the quadratus lumborum muscle anteriorly to the anterior iliac spine. Opens into an abscess cavity, communicating with the perforated colon. Recovery.

Case XI. Weinlechner ("Wien. med. Blat.," 1882. "Ileus in a Man Aged Fifty-two," No. 44).—Laparotomy; incision in median line. Death from peritonitis eighteen hours after. Autopsy shows perforation of appendix vermiformis and perityphlitis.

Case XII. A. Schmidt ("Wratsch.," 1881, No. 51, and "Centralbl. für Chirurg.," 1882, No. 47).—Slow purulent peritonitis in a man aged twenty-one. By aspiration, a thin purulent fluid is obtained. Laparotomy. Incision extending from the navel to the symphysis. The whole peritoneal cavity filled with pus; about five pounds. Removed. Drainage, etc. Complete recovery.

Case XIII. Gussenbauer ("Wien. med. Blat.," 51, 52).—Sword-swallower, aged nineteen, during one of his performances breaks the blade in the œsophagus. The lower fragment is pushed into the stomach by the father, as the boy seems to be choking. On admittance, an examination is at once made, but fails to detect the body either in the œsophagus or stomach. Peritonitis developing, gastrotomy is performed, with extraction of the fragment, which is 27 ctm. long. As no perforation can be detected, closure of the gastric and abdominal wound.

Death. Autopsy shows septic peritonitis, wound of the œsophagus 14 ctm. above the cardia, and a perforation at the fundus of the stomach.

Case XIV. Kocher ("Corresp.-Bl. f. schweiz. Aerzt," Nos. 23, 24).—Gunshot wound of the stomach, in a boy of fourteen, quickly followed by peritonitis and collapse. Laparotomy three hours after. Wound of stomach closed by catgut sutures (Lembert's); closure of abdominal wound. Recovery. Patient out of bed seventeen days after.

Case XV. Sonnenburg ("Berl. kl. Wochenschr.," 142, 1885).—Rupture of the bladder in a man aged thirty-six years. Laparotomy after the establishment of acute symptoms. Abdominal cavity is found filled with urine mixed with fibrinoserous fluid, and signs of peritonitis. The rupture is situated at the inner side of the bladder. It is found impossible either to unite the ruptured part or to sew the bladder to the abdominal wall. Drainage of abdominal cavity. Death eight days after from infiltration of urine and septicæmia.

Mikulicz ("Tageblatt d. Versamml. deutsch. Naturforsch. und Aerzte," Magdeb., 1884, 1, viii, 224).—Mikulicz performs laparotomy in all cases of injury, whether direct or indirect, to the stomach and intestines, even where peritonitis is already present. He cites the four following cases:

Case XVI.—Laparotomy for rupture of the stomach in a man aged twenty-four. Perforation found at the lesser curvature, and is probably the result of extreme dilatation of the stomach. Abdominal cavity is full of fragments of partly digested food. Death three hours after operation.

Case XVII.—Symptoms of obstruction and ileus following a diarrhœa (three weeks' duration) in a young man. Diagnosis: strangulation of the gut. Laparotomy is performed, and about one litre of fibrino-serous matter is removed from the abdominal cavity. Volvulus present and reduced. Recovery from operation, but death three weeks after from intercurrent pneumonia.

Case XVIII.—Perityphlitis followed soon after by symptoms of incarceration. Laparotomy (incision in linea alba). Two litres of fœtid purulent matter are removed from the abdominal cavity. Death five days after. Autopsy shows a perforation of the intestine.

Case XIX.—Acute signs of ileus and incarceration in a young man. Laparotomy. One litre of fœtid pus and a number of pieces of undigested potato found in the abdominal cavity. A perforation is also discovered, on the left side, involv-

ing the ileum, about 6 mm. long and 4 mm. broad. No cause can be found for the perforation except that it is a typhoid ulcer in a case of typhoides ambulatoria. Edges of perforation united by sutures. Rapid recovery.

Case XX. Brugisser ("Corresp.-Bl. f. schweiz. Aerzt").—Acute signs of ileus strangulation and peritonitis in a man of seventy-four. Laparotomy; incision parallel with Poupart's ligament. Resection of strangulated bowel. Recovery.

Case XXI. Lloyd ("Brit. Med. Jour.," March 24, 1883).—M. L., a domestic, aged nineteen, was admitted to Woman's Hospital late in the evening of February 23d. She had been accidentally shot in the abdomen three hours previously. No shock and but little vomiting. Bullet had entered slightly to the left of the median line immediately above pubes. Finger passed readily into peritoneal cavity. Patient becomes steadily worse, and on the 26th has constant vomiting, severe abdominal pain, a temperature of 99°, and a thready pulse. Laparotomy in the evening; abdominal section at once followed by escape of a fœtid, thick, brownish fluid. The intestines are matted together. A coil of gut, hooked from the left iliac region, has in it a ragged wound three quarters of an inch in diameter. Abdominal cavity washed out with plain lukewarm water, a glass drainage-tube inserted, and perforated gut stitched to the center of the abdominal wound. Patient never rallies, and dies in collapse one half hour after. Autopsy shows that bullet has contused the apex of the bladder, cut through the free edge of a coil of intestine, perforated the mesentery and lies between it and the mesocolon.

Case XXII.—Savage ("Brit. Med. Jour.," April 14, 1882) reports seventy cases of abdominal section performed that year. Six laparotomies during *presence of subacute peritonitis with more or less exudation*. All the patients recovered.

Case XXIII. Bouilly ("Bullet. de la soc. de chir.," 8 août).—In a man, aged twenty-nine, who has received two hoof blows in the umbilical region, Bouilly performs laparotomy twenty-three hours after the injury, as symptoms of perforation and peritonitis are present. On opening the abdominal cavity a rent 1½ ctm. long is found in the small intestine, with irregular margins. Resection of a piece of intestine 10 ctm. long. Great improvement. Fæces, however, continue to pass through the abdominal wound (a part of which had been left open). On the tenth day examination is made of the fæcal fistula, with the object of curing it, but in the evening the patient suddenly collapses, and next day dies from purulent peritonitis. Autopsy shows that sutures of intestinal wound had separated, that the separated ends had been shut off by exudation from the peritoneal cavity, and that the rupture of an adhesion was probably the cause of death.

Case XXIV. Albanese.—In a man, seventy-six years of age, who, four days before admission, had received a blow upon the abdomen, symptoms of acute ileus and peritonitis become developed. On the seventh day after the injury laparotomy, the incision being over the colon ascendens. A coil of strangulated intestine is found, bound by adhesions to the cæcum. These are carefully separated. Good recovery.

Case XXV. Willet ("St. Bartholomew's Hosp. Reports," 1876, p. 208).—T. F., aged forty-eight, admitted with symptoms of ruptured bladder, the result of a kick over the pubes. Laparotomy in twenty-four hours after development of peritonitis (general). Incision five to six inches long, extending from the umbilicus to the pubes. On opening the abdominal cavity, several ounces of brown urinous fluid escape; a rent is found across the fundus of the bladder three inches and a half long. Edges of rent are brought together by sutures. Sudden death after a temporary improvement.

Case XXVI. Heath ("Royal Medico-Chirurg. Society," Feb. 25, 1879).—Rupture of bladder. Laparotomy. Rent in bladder closed by sutures. Death from peritonitis.

Case XXVII. Tait ("Brit. Med. Jour.," 1878, i, p. 677).—Laparotomy for abdominal tumor, during the presence of acute peritonitis. The tumor is found to be a Fallopian tube distended with menstrual blood. Drainage, etc. Perfect recovery. Tait has done forty ovariotomies during commencing peritonitis. All the patients recovered.

Case XXVIII. Walter ("Med. and Surg. Reporter," Philadelphia, 1862).—Rupture of the bladder in consequence of a kick on the abdominal wall. As no amelioration follows the introduction of the catheter, and as signs of peritonitis supervene, laparotomy is performed. A rent is discovered at the fundus of the bladder two inches in extent. Some extravasated urine in the abdominal cavity. Wound in bladder is not closed, as no urine is seen to escape. Abdominal wound sutured. *Recovery.* Probably the first case in which laparotomy has been resorted to for acute conditions within the abdomen.

Case XXIX. Chaput ("Jour. de méd.," 1880, p. 103).—Laparotomy for perforation of the vermiform appendix by a foreign body during the presence of acute peritonitis. Abdominal cavity filled with fœtid pus. Drainage. Death.

References.—Güterbock ("Arch. f. klin. Chirurg.," 1884, 419) recommends laparotomy and closure of vesical wound in all cases of rupture of the bladder. McCormac (N. Y. "Med. Rec.," p. 477, 1883) advocates laparotomy in cases of gunshot wound of the abdomen.

Case XXX. Tilnig ("St. Petersburg. med. Woch.," No. 44, 1884).—Man, aged nineteen, received while at supper a knife wound four fifths of an inch long in the epigastric region, one inch to the left of the linea alba and three inches above the umbilicus. While the wound was being sutured patient vomited large quantities of a reddish chyme, and afterward pure blood. Laparotomy. Incision six inches long in median line. On section of peritonæum much blood escapes. The finger introduced detects a wound in the left gastro-colic ligament leading to another in the posterior wall of the stomach, through which the mucous membrane protrudes. The edges of the stomach wound are brought together by sutures. Owing to the collapsed condition of the patient, the abdominal cavity can not be thoroughly cleaned. Abdominal wound closed by Lembert's sutures. Quick recovery.

Case XXXI. Taylor ("Lancet," 1884, ii, 589).—Girl, aged fifteen, gives symptoms of acute hydronephrosis. As the symptoms increase in severity, *laparotomy* is determined on. On the morning of the operation symptoms of collapse set in, the cystic tumor, which was before perceptible on the left side, has also disappeared, and the abdomen is very tender. As rupture of the cyst is probable, immediate laparotomy. Incision in median line. Peritoneal cavity filled with urine. As the point of rupture can not be found, the cyst is opened at another place, and the edges of the wound are stitched to the abdominal wound. Recovery with a urinary fistula.

Case XXXII. "Gunshot Wound of the Intestines treated successfully by Laparotomy with Sutures of the Intestines," by William T. Bull, M. D.; read before the New York Surgical Society, January 27, 1885 ("N. Y. Med. Jour.," Feb. 14, 1885, p. 184).—W. McE., male, twenty-two years of age, was brought to the Chambers Street Hospital on the night of November 2, 1884, suffering from a pistol-shot wound of the abdomen. Seventeen hours after the accident laparotomy was performed under strict antiseptic precautions. On opening the abdominal cavity, the intestines were found to be wounded in seven places; these were carefully washed, and the peritoneal edges were then approximated and the line of sutures carefully rubbed with iodoform. The bullet was detected at once lodged in the

upper surface of the sigmoid flexure. Operation lasted two hours. Abdominal wound closed with deep silk sutures, and dressed with an iodoform and borated-cotton dressing.

Six hours after operation cold-water coil applied. After the eighth day convalescence was uninterrupted save for a few sinuses in the line of incision, and at the end of eight weeks the large wound was cicatrized. The functions of the alimentary canal were performed normally, and he was apparently in good health.

Case XXXIII.—Frederick Treves, F. R. C. S., in a paper read before the Royal Medical and Surgical Society of London, on the "Treatment of Peritonitis by Abdominal Section," reports a case in which a large pelvic abscess had burst into the peritoneal cavity, followed by acute peritonitis. Laparotomy under strict antiseptic precautions. Peritonæum showed appearances of acute peritonitis. The whole cavity washed out and a drainage-tube introduced. Patient made a good recovery.

Case XXXIV.—Mr. Howard Marsh, at same meeting, read the history of a case, the patient being a medical student who was attacked with symptoms of sudden and acute peritonitis. Laparotomy; about two pints of fœtid pus evacuated. Whole cavity washed with sol. acid. carbol., 1 to 60, and a drainage-tube introduced. Recovery.

In the discussion which followed the reading of Treves's paper, Bryant, Thornton, Powell, Barwell, Goodhart, and Meredith were in perfect accord in commending the practice carried out in the two cases noted.

Case XXXV.—Omental abscess, rupture into peritoneal cavity. Laparotomy. Recovery. T. H. Burchard.

On August 20, 1883, I was requested by Dr. Frederick D. Lente to see Ephraim Wells, aged twenty-five, a colored waiter, employed in one of the smaller hotels in Saratoga. For some three weeks Wells had been confined to bed suffering from a severe cellulitis of the abdominal walls. Several superficial abscesses had formed, which had been located by Dr. Lente.

He had suffered intense abdominal pain, temperature fluctuating from 101·6° to 104·5°, and was rapidly emaciating. For six or seven days prior to the present complication his abdomen had become tympanitic and the pain more diffused. For forty-eight hours there had been excessive hiccough and frequent retching of green mucus. On the night of August 19th he took surreptitiously four compound cathartic pills. At seven o'clock on the morning of the 20th Dr. Lente was summoned, and an hour later I saw him.

He was lying with legs flexed, abdomen moderately distended and breathing thirty-two times a minute; his pulse was 120 and his temperature 102·2°.

Examination showed an indurated condition of the tissues of the hypogastric and left hypochondriac regions, the integument being somewhat erysipelatous in appearance. The indurated mass appeared to involve the entire thickness of the abdominal wall, and was about six by seven inches in diameter. Both Dr. Lente and myself thought we detected deep-seated fluctuation, and, although a Lüer's aspirating needle failed to give pus, at Dr. Lente's request I proceeded to evacuate the abscess. Dr. William Curtis, of Philadelphia, gave ether.

My incision was made in the median line (deep-seated fluctuation appearing more distinct there, although the principal part of the induration was slightly to the left), and extended from an inch below the ensiform cartilage downward to the umbilicus.

Just as I reached the linea alba, at a depth of fully two inches and a half, something was felt to suddenly give way beneath the hand, as though an abscess had burst within the peritoneal cavity. Although it was thought the patient would certainly die, it was determined that what little chance he had depended upon giving vent to the pus anteriorly. The incision was extended through the linea alba and into the great omentum, which was adherent to the abdominal wall and the seat of the abscess.

Omentum, intestines, and mesentery were matted together in one inseparable mass, and pus of an extremely fœtid odor welled from the cavity of the belly. I should say fully a quart escaped.

The patient grew rapidly weaker. Inhalations of ammonia and amyl and hypodermics of whisky were freely used. Warm milk-punch was injected *per rectum*.

The patient rallying, the incision was prolonged below the umbilicus, so as to get beneath the abscess, and so thoroughly wash out the abdominal cavity.

Fully a gallon of warm carbolized water (3 per cent.) was thrown gently in among the matted coils of intestine. The walls of the abscess cavity were sparingly dusted with iodoform, and two rubber drainage-tubes were inserted. The upper and lower ends of the incision were sutured with silver wire; the median portion above the umbilicus was purposely left open to permit of free drainage.

A pad of oakum, wrung out in sol. hydrarg. bichlor., 1 to 1,000, was placed over the entire wound, and a light bandage applied.

The patient rallied poorly from the operation. Hiccough and vomiting continued the entire afternoon, the pulse most of the time being scarcely perceptible. 2 P. M., pulse 140, temperature 103·4°, respiration 26; 5 P. M., pulse 136, temperature 104·6°, respiration 30.

Cracked ice and small portions of champagne frappé were given by the mouth, and enemas of beef peptonoids and milk punch were given each four hours. Morphine, atropine, and digitalis were given hypodermically, p. r. n. Ice-coil on abdomen.

August 22d.—5 A. M., pulse 130, respiration 28, temperature 100·6°. Sleeping quietly. Has had during the past twenty hours morphine 2½ gr., atropine ¼ gr., tinct. digitalis ♏ xl. 4 P. M., pulse 124, respiration 27, temperature 101·4°. Wound discharging freely. No hiccough or vomiting.

23d.— 8.30 A. M., pulse 118, respiration 24, temperature 100·2°. Comfortable night. 3.30 P. M., pulse 116, respiration 26, temperature 100·4°. Morphine 1¼ gr. in twenty-four hours. Takes peptonized milk and iced champagne.

24th.—Vomited once during the night. General condition excellent. Wound discharging comparatively little. 9.45 A. M., pulse 115, respiration 22, temperature 99·8°.

26th.—Improving in every respect. Abdominal induration disappearing. Removed one drainage-tube and one stitch. Ordered a tonic—iron, quinine, and strychnine.

29th.—Removed all stitches. Incision about one half inch long. Removed rubber tube, and inserted one of decalcified bone.

September 2d.—Patient convalescing rapidly. Leaving Saratoga to-day. Dr. Lente took entire charge of the case. A few days after, Dr. Lente returned to Cold Spring, and I never saw him again alive. I learned, however, that Wells left Saratoga about the last of September in excellent condition. Most diligent inquiry has failed to find his whereabouts since.

Now, if these forty cases, with twenty-four recoveries, teach anything, they teach not merely the feasibility of such operations, but, more than that, they give us legitimate ground for encouragement in fully sixty per cent. of these otherwise hopeless cases.

In contrast with the foregoing, permit me to give very briefly the history of my sixth case of perforation of the

appendix vermiformis, and, for personal reasons, I desire to omit all names and dates:

I was requested by Dr. —— to see Miss —— in consultation. She was twenty-two years of age, and generally had enjoyed good health. Three months before she had had an attack of perityphlitis, which had lasted about three weeks. A small mass of induration, of about the size of a billiard-ball, was still left. She had had another attack sixteen months before.

On the evening prior to the present attack she had been at a party, danced excessively, got overheated, drank considerably of cooling beverages, and in going home and after she retired had chilly sensations. On awakening about 8 A. M., feeling "uncomfortable in her old spot," she took a large saline. This was followed by two copious movements. During the second she experienced a sudden sharp, darting pain in her right side, and immediately fainted. I saw her about noon. She was then in excellent condition—pulse 108, temperature 100°, abdomen moderately distended; some hiccough and nausea. Pressure over the tumor produced sharp pains. Stethoscopic examination over the cæcum gave distinct fremitus and crepitation. I diagnosticated unhesitatingly perforation of the bowels, and urged an immediate operation. My advice was not accepted. At nine the following morning I was summoned hastily, and to "be prepared to operate." The condition of things had now entirely changed. The patient was semi-moribund. Abdomen enormously tympanitic. Pulse 140, and intermittent. Naturally, an operation at this period would have been worse than useless. The patient died two hours later, or twenty-seven hours from the commencement of the attack. It was with melancholy interest that I saw the autopsy reveal a minute perforation at the base of the appendix not three lines in diameter. The appendix was bound down by old adhesions. There was the faintest exudation of lymph immediately around the perforation.

Austin Flint, in his last edition, in speaking of septic peritonitis (Flint's "Practice," p. 590), says: "The time may come when paracentesis abdominalis will have been proved to be as applicable to certain cases of peritonitis as are thoracentesis, injections into the pleural cavity, and a permanent opening in the chest in cases of suppurative pleurisy." In the light of these cases, I submit, Has that time not already come?

Regarding the medical treatment of peritonitis, there are some points of special interest worth considering, and, first, as to the opium treatment. Opium is our sheet-anchor in the treatment of peritonitis, and yet, indispensable as the drug is, there are certain conditions which arise in the course of the disease in which the drug can only be used with the greatest caution. The indiscriminate use of opium, even in peritonitis, is quite capable of doing more harm than good.

The symptoms of peritonitis vary with the extent, severity, and the causes which produce it. When the disease develops gradually, as from a pre-existing visceral inflammation, for some time there may be little or no constitutional disturbance. When it develops suddenly, however, and particularly if from *internal traumatism*, as hernia, perforation, or other intestinal injury, this condition of *shock* enters as a very important element in the development of symptoms, and the treatment must be varied accordingly.

This initial collapse of peritonitis is a subject upon which too little has been said, and yet its treatment is of most signal importance. I have seen it persist for hours after well-pronounced peritonitis had developed, as evidenced by increasing meteorism, increasing abdominal tenderness, and a rising temperature, and yet the while the patient lying listless or semi-conscious, with limbs extended, with features pinched and shrunken, and a pulse scarcely perceptible.

A most remarkable case of this kind occurred in my practice a few years since. A young gentleman, John H., aged about twenty-six or twenty-seven, came to my office one morning complaining of a left epididymitis. As the inflammation was of unusual severity, I sent my assistant, Dr. L. D. Woodbridge, to his home to apply half a dozen leeches over the cord in the left inguinal region. About midnight I was summoned to see him, as he was suffering severely.

Dr. Woodbridge responded to the call and found his pain was less, but that he was rapidly sinking into a condition of collapse. At 2 A. M. Dr. Woodbridge wrote that "Mr. H. was evidently dying." I went at once, and found my patient unconscious and almost pulseless. His respirations were very shallow, and at times would stop altogether. His pupils were widely dilated and irresponsive. Superficies of the body pale and cold. Rectal temperature 96°. Abdomen greatly distended, and pressure on it would cause a reflex regurgitant movement in throat and an expression of pain. During the early afternoon his temperature rose to 102·6° and he became deeply cyanotic.

Dr. Loomis saw him at 2 P. M., confirmed the diagnosis of peritonitis, and said the patient, being then comparatively pulseless, would certainly die. At 5 P. M., after fifteen hours' constant labor, keeping up artificial respiration all the while and feeling that he could survive but a very few minutes, Dr. Woodbridge and I left the house.

At 6.30 P. M. we were recalled, to find him slowly regaining consciousness. He subsequently fully rallied, passed through an unusually severe peritonitis, and is now well.

In speaking of treatment, the text-books generally recommend, "as soon as the unmistakable symptoms of peritonitis are developed, administer at one dose from two to five grains of opium, or from one half to one grain of morphine."

And yet physiological experimentation has proved that collapse, such as existed in this case, is dependent upon vaso-motor paresis, and the deeper the involvement of the sympathetic the more profound the collapse.

Now, this is a condition of the system in which opium, even in moderate doses, is poorly borne. Infinitesimal doses of morphine in conjunction with atropine, by mitigating pain and securing nervous tranquillity, undoubtedly exert a favorable tonic influence upon the heart. Large doses increase the paralysis of the cardiac inhibitory center and still further cripple that organ.

This is no visionary condition of affairs, for I have more than once seen a heart feebly endeavoring to rally from the

shock of a commencing peritonitis well-nigh overwhelmed by a dose of morphine that the text-books would justify, and one which a few hours later would be insignificant.

Another and very important fact to be noticed in the commencement of peritonitis, and governing greatly the freedom with which opium may be used, is the perplexing discrepancy that ofttimes exists between the severity of the pain and the apparent hard, tense, wiry pulse on the one hand, and, on the other, the very great heart-feebleness.

Under such circumstances, every dose of opium given, unless guarded by atropine or digitalis, jeopardizes the heart, and no dose should be administered under such circumstances without previous careful cardiac auscultation.

There is another condition, developing later in the history of the disease, in which the administration of morphine in large doses is equally prejudicial, and upon which condition current literature is likewise, unfortunately, silent.

I refer to the hypostatic pneumonia which, owing partly to the patient's asthenic condition and partly to pressure on the lungs from excessive tympanites, is so apt to develop at that time.

Here, too, we have an important inhibitory center, the respiratory, paralyzed from carbonic-acid-gas poisoning. In addition, we have lungs badly compressed, with blood imperfectly aërated sluggishly flowing through them; portions of the pulmonary structure are consolidated, either from simple stagnation of the blood or from lobular inflammation.

At this stage a slight overdose of morphine might arrest the respiratory act entirely. Yet I have seen its use persisted in under these very conditions.

When the disease has reached this point and cyanosis begins to develop, I believe little is gained from pressing opium, and it is wise to suspend its administration except at infrequent intervals, giving it only to meet some special indication, and guarding it carefully with digitalis, atropine, or ammonia. At this period stimulating hypodermics should be freely resorted to; dry cups to the lungs are of signal benefit, and inhalations of oxygen often tide us over an ugly complication.

In a case of peritonitis under my charge last winter—that of a young lady of twenty, in the third week of typhoid—my assistant, Dr. Henry A. Mandeville, and myself fought day and night for nearly a week a temperature that fluctuated from 103° to 106·6°, until at last she went into unconsciousness from respiratory failure and carbonic-acid poisoning. Although the cyanosis involved the entire body, and she had been practically pulseless and unconscious for eighteen hours, nevertheless, under the atropine and other stimulants that were injected, and the oxygen inhalations that were given, she rallied and regained consciousness.

Regarding the use of opium, *freedom from pain* is the ideal condition to be secured, irrespective of the quantity of the drug administered. When this is attained, sleep from which a patient can be readily aroused follows as a natural consequence. Opium, or its alkaloid, morphine, should be administered. Personally, I prefer the hypodermic administration of morphine, not alone from the simplicity and certainty of its administration, but, what is of more consequence, the absolute knowledge it gives us of the exact quantity of the drug our patient is receiving. Given by the mouth, how much is absorbed and how much lies dormant in the stomach is purely a matter of conjecture.

Several years since a patient of mine, convalescing from peritonitis, passed a curious mass at stool several days after the discontinuance of the drug. Upon examination, this proved to be a collection of opium pills that had been prepared at one of the most reliable pharmacies in the city.

I am confident that, had this amount of opium been absorbed, it would have killed my patient, in which event the death would naturally have been attributed to the peritonitis.

Objections have been raised against the combination of atropine with morphine, it being alleged that the physiological antagonism that naturally exists between these two drugs tends to render the development of symptoms irregular, and their interpretation more perplexing and obscure.

Undoubtedly atropine does produce a marked change in the patient's appearance, and certain very characteristic changes in the phenomena of the disease; but these changes, we believe, are in every way favorable to the patient.

There is no one drug in the treatment of collapse—whatever be its cause, whether traumatic or from disease—in which more implicit confidence can be placed than in atropine. Owing to its stimulating action, the heart gains strength, the respiratory act deepens, and the phenomena of shock yield in a surprising manner to those of traction. In the later stages of peritonitis, especially when the heart and lungs fail and when gastric regurgitations and hiccough are rapidly exhausting our patient's vitality, I have obtained results that were simply marvelous from the administration of one or more hypodermics of atropine, varying in strength from one sixtieth to one tenth of a grain each, and given either alone or in combination with morphine, digitalin, ammonia, or alcohol, according to the special indications existing.

The contrast in the appearance of two patients—one being treated with atropine in combination with morphine, and the other with morphine alone—is most marked, while in moments of special exigency the value of this drug is inestimable.

The amount of morphine that should be administered varies naturally with the patient's susceptibility, the severity of the disease, and the amount of pain.

Each patient in these particulars is a law to himself, and no rule could be formulated that, in a general way even, would apply to individual cases. The remarkable tolerance of morphine in peritonitis is too well known to require more than a passing mention, and yet, since adopting the hypodermic method, I have been surprised to see how little was generally required, as compared with the immense doses formerly given by the mouth.

After being brought to a condition of partial narcosis there have been comparatively few cases, except those of a septicæmic nature, that have required more than two grains of morphine a day; although in one case attended by Dr. Loomis and myself, after giving three doses of two grains

each, hypodermically, an hour apart, I gave one grain, hypodermically, each hour for twenty-seven consecutive hours without entirely controlling the pain or materially reducing the frequency of the respirations, which varied from twenty-five to thirty a minute. The patient recovered, having received during the first five days of her sickness sixty-three grains of morphine hypodermically.

External Applications.—Much has been said of the efficacy of external applications—used either hot or cold.

Poultices are still used by many. Until within the last two years I employed them exclusively. Upon what therapeutic principle their use was based I did not know then. I do not know now. Under three conditions only can I conceive of any physiological reason for their employment: First, in the commencement of a peritonitis, by their sedative effect upon peripheral nerves, they may assist in lulling pain; secondly, during the passage of urinary or biliary calculi, or in intestinal colic, they may assist in relaxing spasm; and, lastly, during the stage of decline they may hasten the absorption of inflammatory products. For these reasons a poultice is indicated; otherwise they neither control inflammation, reduce temperature, nor lessen tympanites, all of which is done, and with perfect comfort to the patient (provided the temperature of the water is reduced gradually), by the employment of the ice-coil.

If experimental physiology has taught us anything, it is that cold applied to peripheral sensory nerves controls the afflux of blood to those parts supplied by the vaso-motor nerves that inosculate with such sensory branches.

The sympathetics distributed to the intestines and peritonæum arise from the solar plexus, the sensory filaments being the lumbar nerves which supply the wall of the abdomen. Ice applied to the abdomen constricts the blood-vessels of the intestines and peritonæum, and it is in the reflex contraction of these blood-vessels that the benefit resulting from the application of cold to the abdomen finds its physiological explanation. Poultices are not curative. Cold, judiciously employed, lowers temperature, reduces inflammation, relieves tympanites, and secures nervous tranquillity. There is but one way of employing cold, and that is by the ice-coil. This can be readily extemporized from either lead or rubber tubing.

For diet nothing is comparable with peptonized milk, to which additional cream may be added if desired. Valentine's beef-juice, beef-peptonoids, and Leube's meat solution furnish valuable nitrogenized preparations.

For the relief of tympanites much depends upon whether the gas is within the cavity of the peritonæum or in the intestines. If the former, a fine aspirating needle may be introduced, and with immediate relief. If the latter, a long tube may be passed up the bowel and an ounce or more of some warm aromatic solution injected. Gas must not be expected to escape through a tube occluded with fæces.

Large fæcal masses not infrequently prevent the escape of flatus by blocking up the rectum. Under such circumstances a large enema of flaxseed tea, in which some ox-gall has been dissolved, may be injected with benefit. A patient of mine, who was once rapidly succumbing to increasing tympanites, was saved by this simple procedure.

Pneumatic aspiration of the intestine I regard as neither surgical nor safe.

As in the case Professor Polk, reported at the Obstetrical Society, I have seen gangrenous inflammation with fæcal extravasation follow the puncture.

Turpentine stupes I resort to more out of respect to tradition than because of any very positive benefit I have ever seen follow their use in general peritonitis.

When turpentine is pushed to any considerable extent, I fear damage to the kidneys.

I have seen both strangury and hæmaturia follow its external application. In two cases I have noticed a marked increase of albumin in the urine following its employment. A discontinuance of the stupes caused a total disappearance of the albumin in one case, and a considerable reduction in the other.

Independent of the fact that Bright's disease is of itself a frequent cause of peritonitis (Habershon's statistics give 63 cases of Bright's disease as the exciting cause of 301 cases of peritonitis [" Med. Times and Gaz.," Dec. 13, 1859]), the anatomical position of the kidneys renders them prone to take on inflammation whenever the peritonæum is inflamed. Hence I have often questioned if a powerful irritant to the kidneys—as turpentine is—does not sometimes add additional irritation to these organs.

Daily and frequent urinary examinations should be made, for more than once has the timely application of cups and a digitalis poultice over the kidneys saved for me the life of a patient who was insidiously developing a nephritis which, without such examinations, would never have been suspected.

Last, but by no means least, the successful treatment of peritonitis demands a personal devotion and attention involving complete abnegation of self.

THE OPERATION OF EPISIOTOMY.

By REYNOLD W. WILCOX., M. A., M. D.

The operation of episiotomy does not seem to have received, at the hands of English and American writers on the subject of obstetrics, the attention to which its merits entitle it. In the majority of obstetrical treatises the subject is dismissed in a few lines, or no allusion is made to it. If, on the contrary, it has attracted the attention of the author, it is often superficially discussed, or his erroneous preconceived ideas are apparent in his treatment of this subject. To one who has seen this operation as one of frequent, even daily occurrence in the lying-in wards of Vienna, this appears incomprehensible. It is the writer's intention to briefly point out its advantages and results, and, if possible, to deduce some impartial conclusions.

Episiotomy is no new operation, nor is it an abandoned one recently resurrected, but one, although influenced by the fluctuation of obstetrical opinions, in uninterrupted use for more than a century. If we read aright, the name was suggested by Ould, in his "Treatise on Midwifery," in 1742,* although Michaelis was the first to perform it, in 1799. At the next confinement, ten years later, the same

* Parvin, in "Trans. of the Am. Gyn. Soc." for 1882, vol. vii, p. 151.

perinæum was yielding and in excellent condition, but showed a fine cicatrix from the operation.* A little later we find Elias v. Siebold † strongly advising this operation. Frequent allusions are met with in German obstetrical literature, until we find the most complete exposition of this operation in an elaborate article, by Credé and Colpe, in the "Arch. f. Gyn." for 1884.‡ The operation consists in making a small incision, often a subcutaneous one, in the *rima vulvæ*, and is never an extensive and complete laying open of the vagina, as has been described or as is often considered to be the case by those who have not seen it performed. In fact, it hardly deserves to be dignified by the term "operation" if one looks at it only from the standpoint of facility of performance and the slight amount of practice required.

The aim of the operation can best be understood if one considers the causes of dystocia that arise from conditions of the soft parts, or can be remedied by operations upon them. In brief, in performing episiotomy it is intended to avoid rupture of the perinæum, arising from all causes except those referable to the force and character of the pains. The causes of perineal rupture are:

I. From condition of the soft parts.

a. Rigidity, by which we mean that the perinæum shall be anatomically normal—the perinæum of inexperienced obstetricians. In this case the vaginal orifice can be dilated to the size of the child's head, yet the hyperæsthesia of the muscles prevents this end.#

b. A second condition to which this same term is applied when the vaginal outlet is anatomically incapable of full distension, when the surrounding tissues are not fully developed, or, as in old primiparæ, the tissues are inelastic.

c. A condition of the muscular fibers which renders them unable to bear moderate strain, a state of affairs found in tissues for a long time subject to congestions, indeed analogous to the fatty infiltrations and degenerations. ‖

d. Excessive width or length of the perinæum.△

II. From condition of the bony parts.

a. The narrow pubic arch, "male pelvis," or, what amounts practically to the same result, a thickened condition of the urethral structures.

b. Too little inclination of the pelvis.◊

III. On the part of the child.

a. Incompressibility or excessive size of the head.

b. Malpositions and malpresentations.

Lastly, the feeling on the part of the accoucheur that, "if laceration is inevitable, treatment to prevent it can be of no avail." ↕ In the three classes mentioned it is assumed that the conditions present do not exist to such an extent that birth is not possible without other operative or instrumental interference. It is to hasten the result and to avoid the unfortunate consequences of perineal rupture that this operation is demanded.

That unavoidable perineal rupture takes place is proved conclusively by the records of clinics where no one is allowed to practice midwifery until shown competent by examination.

Winckel * states that ten per cent. of all patients suffer laceration. While Hecker,† in over twelve thousand cases, found three and sixty-six hundredths per cent. of lacerations, Spiegelberg,‡ among three thousand cases, found tears over two and a half centimetres long (one inch) in three and one half per cent. of cases; Preiter's# cases, over seven thousand in number, showed tears in three and forty-seven hundredths per cent. of their number.

Considering primiparæ alone, the percentage is much higher, being, according to K. Schroeder,‖ twenty-four and four hundredths per cent. (deliveries in side position); according to Hippold,△ eighteen and seven tenths per cent. In elderly primiparæ, as shown by Ahlfeld,◊ about thirty per cent.; by Hecker,↕ fourteen per cent.; by Cohnstein,↕ three and fifty-eight hundredths per cent.

The relative frequency of lacerations in primiparæ and multiparæ may be inferred from the following figures: B. Schroeder ‡ thirty-four and one half and nine, Kleinwächter ** thirty-four and ten, Olshausen †† twenty-one and one tenth and four and seven tenths per cent., respectively. The last authority, quoted in Lusk,‡‡ believes that fifteen per cent. is not too great for unpreventable tears due to defective distensibility of the perinæum and disproportionate size of the head of the child in primiparæ, although he considers two per cent. too high for multiparæ.

The advantages of episiotomy are not disputed in cases of atresia vaginæ or in any structural contraction.## Granting that a laceration is inevitable, the operation removes it from the median line and locates it in the exact position chosen by the accoucheur. This avoids the danger of a laceration through the sphincter ani, and also relieves the strain upon the recto-vaginal septum, preventing a central rupture.‖‖ Also, as is stated by Elder,△△ episiotomy limits the extent of the lesion. In Credé's cases not a single case of total rupture occurred.

When one compares the spontaneous lacerations, irregular in depth and outline, with the subcutaneous incisions or

the clean-cut operations (the daily practice in Vienna), he can not but mark the difference and marvel that so simple a procedure has attracted so little attention in America. Not only because the incisions are subcutaneous do they unite so readily, often by first intention, without subsequent attention, as in Spaeth's wards at Vienna, but the fact that the edges are clean-cut is important.* Yet Playfair, in his "System of Midwifery," 1880, has apparently changed his opinion, for, while he now admits, as every one does, that incised wounds heal more rapidly than lacerated ones, he believes that a distended perinæum ruptures with edges as clean-cut as if by a knife.† The testimony of the gynæcologist who meets with extensive cicatrices, deep and irregular in outline, in his daily work, proves that a clean-cut spontaneous laceration must be very rare—far more so than our author would have us believe.

A third reason for the more rapid process of healing after this operation is that the gaping observed from retraction of the transversus perinæi muscle in spontaneous laceration is absent.‡ Although the passage of lochia over an open wound is often unattended by general symptoms or retarded healing, yet the artificial lesion obviates any possible danger from this source so long as the dorsal position is maintained.

Finally, the deformity of the vulva is by no means so great as after spontaneous rupture.#

In marked contrast to the anxiety shown in the paper by Credé as to the patient's future is that inferred from the statements, so often met with, more or less frankly made, "that perineal tears are of no significance if they heal without surgical interference."‖ Perhaps even more unfortunate, and fraught with far more disastrous consequences to the patient, is the opinion occasionally met with that these lacerations are very rare, and in the observers' personal experience never have they been encountered.△ Happily, such opinions are fast becoming less frequent, and one may hope that the practitioners may be led to take measures to prevent what they have hitherto left for others to cure.

It has been justly urged that we can not certainly predict that a laceration will occur, and therefore this operation has no clearly defined indications. In an earlier portion of this paper statistics from various sources are quoted showing that, under any and all systems of treatment, lacerations must occur; but to state that one who has had thorough practical instruction—and none other should be allowed to practice midwifery—can not with reasonable certainty predict that the perinæum, if left to itself, will be lacerated, is, to say the least, begging the question. To operate only when the fact that the accident will occur is absolutely certain would be to debar surgical interference, not only in this, but in every other department of medicine. It is true that we must have a wound when we perform this operation; but in Credé and Colpe's cases (*loc. cit.*, S. 159) puerperal ulcers (episiotomy wounds healing by granulation) occurred only nine times in two hundred and seventy-one cases of operation, but little significance need be attached to this statement. It is also true that the wound may be a point for general infection, but the relative probability of this in a wound not exposed to the lochia, as compared with the sloughing, granulating wounds of a lacerated perinæum bathed in a decomposing discharge, is easy to determine. Further, the wounds most dangerous as regards general symptoms are those about the cervix, and not the external ones. That this operation does not prolong the puerperium will be shown in the figures to be quoted hereafter. The operation causes pain, very slight in amount if it be properly done, but by no means to be compared to the pain that it saves by shortening the period of labor and by substituting a rapidly healing for a slowly suppurating wound.

Apparently Adolphus * is totally misinformed as to the character of this operation when he advises the timely use of the forceps, which will render this operation needless, since, even if a perineal laceration could be avoided, a doubtful contingency, the forceps operation is by far more severe than episiotomy.

The weightiest argument of all against episiotomy is the fact that it will not always prevent a laceration. In Credé's cases the laceration occurred in one and four tenths per cent. of his episiotomies, a small percentage indeed when one considers the value of the operation. Leishman's statement,† that the incision will always be extended as the head advances, is unsupported by the facts and is contrary to our own experience. It is conceded that we can not always estimate the extent of the laceration;‡ thus we can not always avoid slight addition to the incision; but even this is far preferable to the spontaneous laceration. The percentage of extensions given above is far too small to condemn the operation.

In performing episiotomy, the left lateral position for the patient is preferable, since the advance of the child is then under perfect control.# The instrument used by Michaelis was a Pott's bistoury; in Leipsic formerly Cooper's scissors, now the usual straight scissors are employed. In Vienna the ordinary blunt-pointed bistoury is employed. Leishman‖ remarks that the finger-nail may be used, "as has been practiced by some of the most distinguished accoucheurs," a fitting commentary upon his knowledge of the operation. The time of the performance of the operation is of no little importance; according to Credé and Colpe,△ the incision should be made immediately after the acme of the pain, because then one knows exactly the length of the cut, and it gives rise to less pain, whereas, if it be made before or during the pain, a sudden and severe labor-pain may be set up and the head be suddenly forced into the world, and the incision be converted into a rupture. On

the contrary, Lusk* advises that it be made at the beginning or end of the contraction. The incision is made two to three centimetres (three fourths to one inch and a fourth) above the frænulum,† toward the tuber ischii—in other words, perpendicular to the rima.‡ In the Vienna wards it is generally submucous or subcutaneous. Spiegelberg # advises that the open wound be made chiefly in the skin. The length of the incision is fairly given as from one to three centimetres, by Lusk‖ as not over three fourths of an inch. One incision only is recommended by Credé and Colpe, to be upon the side which bulges most,△ while Carl Braun◊ and Schroeder‡ seem to prefer the bilateral. The structures divided are, omitting the skin or vaginal mucous membrane the so-called constrictor cunni,‡ or, as Lusk‡ explains, the, resisting ring formed by the constrictor cunni, transversus perinæi, and sometimes the levator ani.

To recapitulate: The patient being in the ordinary side position, the operator, controlling the advance of the child's head with his left hand, takes the blunt-pointed, straight bistoury in his right hand. He inserts it, at the commencement of a labor-pain, between the presenting head and the thinned edge of the vulvar outlet, flatwise, and where the outlet bulges most, generally at the distance above indicated from the commissure. The bistoury is held in this position during the increase and until the acme of the pain, the left hand being likewise kept in place. Immediately after the acme has been reached the edge of the bistoury is turned at a right angle to the edge of the vulva, the head being prevented from being forced out by a sudden exacerbation of the pain; the incision is made outward, from one half to one inch, through the resisting structures. The labor now is conducted as usual, the head, as a rule, passing out at the next pain. In most cases no after-treatment is required, as the wounds almost invariably close by first intention if carefully cleansed. If the operator believes the suture to be necessary, it is done in the following manner: The first suture should enter at the junction of the skin and mucous membrane, at the upper angle of the wound, coming out at the corresponding lower angle, and be tied. The second suture is to cover in the two small surfaces left, the one in the skin and the other in the vagina. This suture passes through the skin into the vagina, over the vaginal wound, out through the skin, and is tied over the skin wound. Iodoform dressing is then applied. The sutures are removed about the sixth day, and one will find, with difficulty, a fine cicatrix, if he examines the parts, at the end of the third week.

In presenting the numerical results of this operation, the writer is indebted to the excellent paper of Credé and Colpe, as indeed all others who are interested in this procedure must be. One of the strongest objections to this operation has been that it offers a point for general infection. That infection more frequently results from coincident tears in the vagina or cervix is stated above; the observations in the Leipsic clinic confirm this view, there being a difference of only three tenths of one per cent. in cases of puerperal fever in patients suffering from injured perinæum over those occurring when the perinæum was intact. Indeed, among the fatal cases of puerperal fever, two hundredths of one per cent. represent the difference of death-rate in favor of *injured* perinæa, conclusively showing that the condition of the perinæum had nothing to do with either mild or severe cases of puerperal fever. Nor are figures wanting to show that this operation shortens the time of convalescence, for the cases of episiotomy that remained over fourteen days were twenty-one and two tenths per cent.; cases of ruptured perinæum remaining over the above time, twenty-six and nine tenths per cent; cases of rupture in spite of episiotomy remaining over the same time were thirty-one per cent. of the whole number. The percentage of all cases of injured perinæa remaining over fourteen days in the hospital was twenty-three and one tenth, while the corresponding percentage for episiotomy cases was twenty-one and two tenths. That is to say, the percentage of patients undergoing the operation of episiotomy, and who, without this operation, would have suffered rupture of the perinæum, whose convalescence necessitated a stay of more than fourteen days in the hospital, was less than that of ruptured perinæa requiring the same length of after-treatment.

To explain the cases of rupture in spite of episiotomy, twenty-nine in number, it is necessary to state the conditions present. Fifteen of these patients gave birth to children of over thirty-five hundred grammes (seven and seven tenths pounds), four suffered from vaginitis granulosa, three underwent forceps operations, and in one case the blades were badly placed. Of the remaining fourteen cases, three were vaginitis granulosa, three syphilis, one was an antero-frontal presentation, one a case of hydrocephalus, two tears were caused by the shoulder, thus leaving four cases in which rupture took place after incision, which only shows that in these four cases the incision was not long enough, and is in no case to be considered an argument against the operation.

No further argument seems to be necessary to show that incision is preferable to spontaneous rupture.

To demonstrate the effect of the operation upon the frequency of rupture, the statistics of one thousand cases of primiparæ, delivered by five successive assistants at Leipsic, are here given:

	Percentage of Incisions.	Percentage of Ruptures.
First assistant	10·3	20·7
Second "	20·4	11·8
Third "	26·3	11
Fourth "	28·5	7·4
Fifth "	32	7·2

From this the conclusion may be drawn that, as the operation of episiotomy becomes frequent, in just the same ratio do perinæal ruptures become infrequent.

TYPHOID OR ENTERIC FEVER.

(ABORTIVE TREATMENT.)

By EDWIN R. MAXSON, M. D., A. M., LL. D.,
SYRACUSE, N. Y.

Definition.—*Typhoid* or *enteric* is a continued fever, and, when not arrested, is liable to be of long duration, may be attended with diarrhœa, and is usually characterized by intestinal lesions, an eruption of small rose spots, sudamina, and often enlargement of the spleen and mesenteric glands.

Symptoms.—At first the appetite may fail, the tongue become furred, and very soon there is headache with general depression, and muscular weakness with wandering pains, the patient being indisposed for exertion of any kind, mental or physical.

After an indefinite prolongation of these premonitory symptoms there may be chilliness, more or less marked. The headache increases, being sometimes attended with epistaxis. The prostration becomes greater, with sensations of chilliness along the back, alternating with flushes of heat.

If typhoid fever is prevailing in the vicinity, or the patient has been exposed to the causes known or supposed to produce the disease, the physician, if a person of ordinary sagacity and diagnostic ability, will suspect the disease. If the suspicion is well founded, in addition to the symptoms already stated, there will be found the usual symptoms of the febrile state. The pulse is increased in frequency; the temperature rises; the tongue is coated of a white or yellowish color, of various degrees of thickness; and the urine is diminished in quantity and high colored, as a rule.

If, on further examination, no local inflammation can be found to account for the pyrexia, and the patient looks heavy and oppressed, being more prostrated than the duration of the illness, without the influence of the typhoid poison, would be likely to have caused; and if the abdomen is tumid, with slight tenderness over the right iliac fossa, or even if there is not, with the other typhoid or enteric symptoms—the physician of discretion, prudence, and common sense will not need to wait for further symptoms, which will, of course, be developed at a later stage of the disease, the result of a *continuance* rather than essential symptoms of the disease, but will resort to proper means for its arrest. For he may thus destroy the poison, reduce the temperature by gentle perspiration, subdue the intestinal incipient disease, equalize the circulation, sustain the sinking powers of the system, and very generally thus arrest not only the local but the general disease.

But when these plain indications are not fulfilled, or if the attempt fails, as may sometimes happen as the disease progresses, other symptoms are developed, as might be expected.

The temperature rises from day to day, being from one to two degrees higher in the evening than in the morning, by the third or fourth day being 103° or 104° F., perhaps, as a rule. And by the end of the first week there will have been developed the symptoms peculiar to the *continuance* of the disease, as the flushed face, pulse from 80 to 120, often a cough, tumid abdomen, a gurgling of liquid with gas, and slight tenderness in the right iliac fossa, with either constipation or diarrhœa, turbid urine, and sometimes the appearance of small rose spots of the size of a pin-head over the abdomen and chest.

By the end of the second week sudamina will usually have appeared. The patient may lie mostly on the back, red patches being on the cheeks. The hands have become unsteady, delirium may attend, and the sudamina may have extended over the chest, neck, and other parts of the body. The spleen may become enlarged, and the diarrhœa, if present, more troublesome; and from the latter part of the second week onward various complications, as pneumonia, hæmorrhage, or perforation from intestinal ulceration, may occur.

By the end of the third week the patient may be deaf, dull of comprehension, and half unconscious. The body becomes emaciated, the skin harsh, the muscles wasted, the tendons contracting or rising up, and, if the disease passes on uncontrolled, the tongue becomes dry and dark, the pulse indistinct, the heart weak, the abdomen distended, the stools involuntary, and the patient generally, either with retention or incontinence of urine, passes on to dissolution, either by asthenia or else from some local lesion or complication, as hæmorrhage, perforation, peritonitis, albuminuria, pneumonia, pulmonary gangrene, pleurisy, thrombosis, embolism, or suppurative parotitis, which may have supervened.

But, should the patient rally, the temperature gradually falls, the pulse becomes less frequent and more distinct, the tongue cleans, the abdomen subsides, the diarrhœa ceases, and the strength gradually returns, subject, of course, to relapse and various accidental complications that may arise.

Diagnosis.—When typhoid or enteric fever is prevailing in a locality especially, or, when it has not been prevailing, if the patient has been exposed to influences known or supposed to produce the disease, and there are symptoms of unaccountable weakness, with loss of appetite and a look of illness and prostration not dependent upon some local inflammation and altogether disproportionate to any assignable cause other than the typhoid poison, the disease should be suspected.

If on a careful examination, now, not only local inflammations, but tubercular meningitis, acute pulmonary tuberculosis, gastro-intestinal catarrh, pyæmia, ulcerative endocarditis, etc., can be excluded, and, in addition to the symptoms already enumerated, the patient has a severe headache with epistaxis, and a temperature of 101° or 102° F. in the morning, or at evening 103° or 104°, the case may very safely be regarded as typhoid or enteric fever; and an effort should be made for an arrest of the disease.

If the disease can be arrested at this stage, no further symptoms peculiar to it need be developed. But, if not arrested the first week, there may be a diarrhœa, tympanites, the rose-colored eruption by the tenth and sudamina by the

fourteenth day, obtuseness of hearing, delirium, coma, getting down in bed, *confirmatory* but not necessary for correct diagnosis, being rather consequences of a *continuance* than necessary symptoms of the disease, if arrested during the first week. Taking, then, all these precautions, it is my opinion that very few, if any, mistakes need be made in the early diagnosis of typhoid or enteric continued fever.

Causes.—It is probable that a multitude of causes may operate in *predisposing* to typhoid or enteric continued fever—such as hereditary predisposition, age, violent physical exertion, damp sleeping-rooms, impure confined air, insufficient clothing, scanty or unwholesome food, impure water, filth, great depression of spirits, taking food at unseasonable hours, the use of tobacco, drunkenness, and the entire train of depressing influences whereby the system may be reduced to a condition in which the fluids and solid tissues of the body are in a more or less abnormal state, deranging the cutaneous, alimentary, and other functions.

The *exciting* cause of typhoid or enteric fever, doubtless, consists of a poison generally derived from a pre-existing case, probably the *typhoid bacillus*, which has been found in the lymphatics, blood, and tissues, but sometimes arising, as all contagious diseases did originally, from an equivaleut poison, "generated anew by the decomposition of sewage" and "of other forms of animal filth." In either case the typhoid poison is "reproduced in the system during the fever, and it appears that its chief, if not exclusive, outlet is in the intestinal discharges."

But while, however, the *contagium* may doubtless be present in the fæces when voided, its virulence appears to be heightened by exposure, warmth, stagnation, and accumulation, probably by a sort of fermentation, which may go on indefinitely, the product becoming mingled with water, milk, and other liquids and even solids, thus producing, especially in towns, quite a general prevalence of the disease. It is probable, however, that the *contagium* may be generated by the "fermentation of fæcal matters, independent of any specific germ introduced in typhoid evacuations," precisely as in the first cases which occurred at the origin of the disease, as already suggested.

The most common vehicle of the poison appears to be drinking water, contaminated through sewage, either when drank alone or with milk with which it has been mixed.

Anatomical Characters.—While the "primary change is in the blood," and in most fatal cases local congestions and inflammations are met with in the lungs and other organs, the "special and characteristic lesions are those taking place in the intestines and mesenteric glands."

The intestinal mucous membrane of the ileum usually "presents the appearance of acute catarrh," the chief seat of morbid changes, however, being in Peyer's patches, consisting of an infiltration of the glands, followed by ulceration.

It appears probable that the first few days of the disease are attended with *congestion and irritation*, with, perhaps, slight *infiltration*. Afterward, if not arrested, infiltration goes on into incipient *ulceration*, and ultimately to extensive *ulceration* or *resolution*.

These stages, perhaps, occupy, as a rule, about a week each in cases not arrested. And it appears that the patches first affected are those "at the lower end of the ileum, near the ileo-cæcal valve," the lesions here being the most extensive and farthest advanced. The ulcerations may involve only the superficial layer of the mucous membrane, or its entire thickness, and in some cases the muscular and even peritoneal covering may be implicated, with or without perforation. Small points of extra-glandular ulceration may also be found scattered along the mucous membrane of the *small* and even *large* intestines. The mesenteric glands are also more or less enlarged, being firm and of a pinkish color. The spleen may also be found enlarged.

Pathology.—Taking into account an hereditary or accidental predisposition, the typhoid poison from a previous case, or generated anew from animal filth, sewage, etc., introduced into the system in drinking-water or otherwise, once in the blood, doubtless not only directly depraves that fluid, but, being carried by it through the brain and all the tissues, prostration—attended with more or less chilliness, and this followed by fever, headache, a torpid skin and liver, with consequent gastro-intestinal irritation, congestion, inflammation, and, if not arrested, ulceration—may be the result, the symptoms, developed during advanced stages of the disease, being a result of its *continuance* rather than essential to the disease if arrested.

Prognosis.—While the poison of typhoid or enteric fever, operating upon a system fearfully predisposed, may, in some cases with bad surroundings, so far deprave the blood, depress the nervous system, and derange the various functions as to render an arrest or even ultimate cure of the disease beyond the power of human skill, I can readily believe, especially if neglected during the early stages, two of which I have had the painful experience of treating during the past ten years; I as firmly believe, from careful observation during that time in a large number of cases, that, with good surroundings, proper care, and judicious treatment in season, nearly every well-marked case may be arrested so as not to require further personal attendance within one week, and on strictly rational, common-sense principles.

Treatment.—On diagnosticating a case of typhoid or enteric continued fever, the blood is found poisoned, the nervous system prostrated from the poison and inefficiency of the depraved blood, the skin and liver are torpid from the same cause, and, as a consequence of all this, the thoracic, abdominal, and pelvic viscera, including the gastro-intestinal mucous membrane, and especially Peyer's glands, from the ileo-cæcal valve upward, are in a more or less congested, irritated, and inflamed condition; and, from a want of due exhalation from the skin, animal heat accumulates, raising the temperature to from 101° to 104° F.

The indications, then, are plainly: to destroy or neutralize the poison in the blood; unload the liver; call the skin into action, thus reducing animal heat; to call the circulation to the extremities; to sustain the powers of the system; to subdue abdominal, thoracic, and other irritations, and especially gastro-intestinal; to suitably nourish; and to keep the patient properly encouraged.

Now, while there are many agencies by which some of

these indications may be fulfilled, I will state only the means which I have found the most convenient and effectual, and by which I have succeeded in arresting within one week nearly every case clearly diagnosticated as typhoid or enteric fever that I have treated during the past ten years.

To destroy the poison in the blood I give to an adult four grains of the sulphocarbolate of sodium every six hours—at 6, 12, and 6 o'clock—dissolved in a teaspoonful of water.

To sustain the sinking powers of the system, and as a further antiseptic, two grains of cinchonidine with ten drops of the muriated tincture of iron are given every six hours, alternating with the sulphocarbolate, in four ounces of warm crust-coffee without milk; and these medicines are continued for at least a week after discontinuing my visits, the doses being gradually diminished at the last.

To unload the liver I give an improved compound cathartic pill at first, and then give one a day if the bowels are confined; but, if not, a grain pill of leptandrin instead till the tongue cleans off, and afterward one only of either, as required for constipation.

To call the circulation to the extremities and the skin into action, thereby reducing animal heat, as it becomes latent in the evaporation of perspirable matter from the surface of the body, a warm foot-bath is used morning and evening till the fever is arrested and the skin becomes soft and of a normal degree of heat, as it generally will within three days by the aid also of warm drinks required for nourishment, and a strict avoidance of everything cold, internally and externally.

But should the headache continue in spite of all this, which is rarely the case, a teaspoonful of blood is taken from the back of the neck by cups, and repeated if necessary, or blisters applied back of the ears or neck.

To subdue thoracic, abdominal, and other irritations, I apply daily from the very first warm sinapisms over the chest and entire abdomen mornings and evenings, taking care not to blister but to keep as near to it as may be necessary, and continue them till every symptom of the local and general disease has disappeared.

Avoiding cold, the patient takes only warm crust-coffee, one half milk, for drink and nourishment, thus favoring the sensible and insensible perspiration; plain nourishing food, at meal times only, when tolerated, being allowed with tea if desired.

To keep up the spirits, the patient is kept dressed and out of bed days as far as consistent with safety, being allowed to recline on a lounge or to occupy an easy-chair, thus securing better sleep nights.

Here, then, my abortive treatment of typhoid or enteric continued fever really ends. But should a case, from neglect, bad surroundings, or inefficient early treatment, continue on for more than a week, I would treat such local inflammations as might have arisen before or in spite of treatment by cups, blisters, etc., and the gastro-intestinal disease especially by blisters to the epigastrium and abdomen if necessary. And the only addition I should make to the abortive treatment already suggested—except to meet emergencies, as diarrhœa, hæmorrhages, etc.—would be to give with the iron and cinchonidine eight drops of turpentine, in emulsion, as an alterative for the gastro-intestinal disease, and two drops of the tincture of nux vomica with the sulphocarbolate, as a tonic for the digestive organs and nervous system, meeting, of course, any other indications that might arise from a continuance of the disease on strictly rational common-sense principles.

Concluding Remarks.—It may not be improper to add, in conclusion, that the treatment of typhoid or enteric continued fever here suggested has been arrived at by careful observation for a term of years, my success in arriving at the abortive treatment having been largely due to my observations with Prof. Lister, in the Royal Infirmary of Glasgow, in 1867, bearing on antiseptics, before the typhoid bacillus was known as the probable cause of the disease, though according admirably with that view as now generally held.

I have found, however, that, in order to succeed in the abortive treatment, the warm foot-baths must be regularly had and continued each time till there is a gentle perspiration, the sinapisms being kept on long enough each time to insure a continued redness all over the abdomen and chest; also to guard against pulmonary complications as well as to arrest the intestinal disease, though short of blistering; and that the drinks must be restricted rigidly to warm crust-coffee, half milk, with warm tea at meal hours, if desired, half milk; absolutely nothing else to be taken into the mouth except such suitable warm digestible food as may be proper at meal hours only, as eggs, toast, etc., and the plain antiseptics, tonics, and laxatives suggested, or their equivalents, though I have found these remedies the most convenient and successful, and therefore recommend them. Finally, I may state here that I have found a corresponding course of abortive antiseptic treatment available in all putrid fevers—as typhus, diphtheria, spotted fever, etc.—and cutting short scarlet fever and measles nearly one half.

No. 208 Madison Street, Syracuse, N. Y., *May 25, 1885.*

ON THE CORRELATION OF ALCOHOL RHEUMATISM, AND PHTHISIS.

By TANDY L. DIX, M. D.,
SHELBYVILLE, KY.

Owing to the feverish state of the public mind as touching the temperance question, he who approaches any proposition looking to the encouragement or supplying an excuse for the use of alcoholic drinks is regarded as perpetrating an act of temerity. But science is positive in presenting facts which, as well as the laws pertaining thereunto, must be strictly observed; and, however desirable it may be to retard the devastation which is being wrought in our midst by the abuse of alcoholic drinks, science can not compromise herself for the sake of expediency, as some moralists do when they teach that the wine mentioned in the Testament was not an intoxicating drink. And he who follows the teachings of science can not err. It is not our intention to produce arguments either for or against temperance, but strictly in the interest of science. The medical man who lets his predilections influence his views in regard to the

chemical and physiological action of alcohol within the human economy is more dangerous to the community than alcohol itself.

In the course of my professional duties my attention was specially called to this subject, and, upon reflection, several reasons presented themselves which favored the proposition that those who use alcoholic drinks enjoy, to some extent, an immunity from rheumatism and phthisis. In order to learn whether facts would tend to confirm or refute this proposition as regards rheumatism, I have considered every case of indulgence within the scope of my acquaintance and memory, and have drawn upon the experience and observation of as many physicians and laymen as my opportunity and acquaintance would permit. I have also considered cases of rheumatism as regards the habits of the patients. In the reckoning, drinkers who suffered with rheumatism which was attributable to specific causes have been omitted.

In gathering information concerning this topic, it is necessary to make close inquiry, and to consider the views which the informant may entertain in regard to the liquor traffic. A bartender can not discover rheumatism among his customers, and the extreme temperance man can discover rheumatism in every one who indulges. The information that I have been able to obtain confirms the proposition, and, if the proposition is true, it must be founded upon physiological and chemical facts which I propose to consider as follows.

In approaching this topic, the first inquiry that engages our attention is the physiological and chemical origin and elimination of the very complex substance—*fibrin*. Fibrin is found in its most perfectly developed state as its exists in the muscles and fibroid tissues, and is held by the blood in solution as a product of both progressive and retrogressive metamorphosis. The following ultimate constituents of *albumin*, *fibrin*, and *casein* show a successive increase of oxygen as we pass from the former to the latter, and a decrease of sulphur and phosphorus. This is the result of the oxidation to which reference will be frequently made as we proceed with the argument:

	Albumin.	Fibrin.	Casein.
Carbon	55·46	54·45	54·66
Hydrogen	7·20	7·07	7·15
Nitrogen	16·48	17·21	15·72
Oxygen	18·27	19·35	21·55
Sulphur	2·16	1·59	·92
Phosphorus	·43	·33	

In the retrogressive metamorphoses the sulphur and phosphorus are converted into sulphuric and phosphoric acids. This is the source of those acids which are found in the urine and perspiration of rheumatic patients. The sulphur and phosphorus being thus extracted from the fibrin, the gases are left to arrange themselves into other forms known to chemistry as osmazome, creatin, creatinin, uric acid, and urea. These transformations are the conditions through which the nitrogenous matters are to pass in order to be eliminated from the system. These successive formations, and perhaps others unknown to chemistry, may be either intra- or extra-vascular—*i. e.*, in the latter case, take place in the muscles or fibroid tissues, where they act as irritants to which may be ascribed the pain and inflammation of rheumatism, and the consequent thickening of the tissues affected and the stiffness of the joints which so commonly attend this disease.

Another product of fibrinous metamorphosis is a low form of protein compound capable of being deposited in all, or nearly all, the tissues of the body, but finds the lungs to be its favored site, and is known to the pathologist as *tubercle*. In support of the view that tubercle is the product of the metamorphoses of nitrogenous matter, whether originating from fibrinous blastema or from fibrin itself, Rokitansky says: "Many blastemata, distinguished for their coagulability, do not rise above the lowest grade of form development, and not alone do they stop at the grade marked out by the process of coagulation, but their ulterior tendency is to liquefy. An example is afforded in tubercle." . . . "Chemically considered, all blastemata for pathological new growths are protein compounds, for the most part in various degrees of oxidation." Again: "In the first place, the ground-work of rapidly solidifying tubercle blastema is, without the least doubt, *fibrin*." And Dr. Glover, in his analysis as quoted by Dr. Aitken, says that very little difference in ultimate composition has yet been detected between recent tubercle and the other so-called compounds of protein.

Upon the hypothesis that tubercle finds its origin in fibrin, an intimate relation between the fibrin-crasis and tuberculosis must necessarily subsist; consequently, an inquiry into some facts and circumstances attending the fibrin-crasis may be made with a hope of finding not only the cause of tubercle, but also a remedy for the evil. And, in addition to these, we may find some interesting facts which pertain alike to tuberculosis and rheumatism. With this threefold purpose in view, we will consider the two diseases in their correlation with hyperinosis, as follows:

1. The two diseases are attended with hyperinosis.

2. The two diseases have a common origin in the causes which produce hyperinosis.

3. The two diseases result from retrogressive metamorphosis of the fibrin.

4. The two diseases find a common remedy in those means which correct the hyperinosis.

In regard to the *first* of these, it is not necessary to adduce evidence of a fact which is already established.

2. That *the two diseases have a common origin in the causes which produce hyperinosis* finds a solution in the conditions and circumstances which surround those who are engaged in pursuits that require great muscular exertion. Among these may be recorded "tumblers," men who perform in the circus-ring, mechanics, miners, and operatives in mills. Now, it is worthy of note that these classes, as a rule, enjoy an immunity from tubercle while most actively engaged in their business; but when their health declines, so that they can not labor so hard, or when, from any cause, they cease to labor in any degree, or change their manner of life from active to sedentary habits, *tubercle finds its most favored opportunity of presenting itself*. We find a most beautiful and convincing illustration of this

principle as it obtains among wild animals when in captivity. These animals, when in their native lands and enjoying a mode of life that is natural to them, are comparatively exempt from tubercle; but when in captivity, they are prone to this disease. "The Austrian runners," Dr Aitken says, "are another class who are instances of breaking down by over-exertion in running at ages unsuited for their strength. They seldom live beyond three or four years, and gradually die of consumption" ("Remains of Mrs. Trench," p. 72). This same thing occurred in the person of a little girl, a near relative of the writer. Her father conceived the idea that his daughter should be actively exercised in the open air, and to this end he would take his daughter on long and fatiguing walks. The result of this vigorous exercise was phthisis pulmonalis. In this case there had not been a trace of tubercle on the mother's side (and the ancestry was known for several generations), and none, so far as the writer has learned, on the father's side. This case may be safely placed to the credit side of muscular exertion.

Another evidence that fibrin is intimately associated with tubercle is found in the well-known fact that mothers afflicted with phthisis pulmonalis enjoy an abatement of the disease during pregnancy; but after childbirth the disease assumes a fresh impetus, and the mother finds in the grave an early termination of her sufferings. This temporary relief is obtained by a consumption of the fibrin in fœtal construction. And, again, there are three periods of life most favorable to tubercle: *First*, in early life, including intra-uterine existence, when the vital forces are exerting themselves in fibrin construction; *second*, when the body has about obtained its growth and there is a surplus of fibrin; *third*, in the declining periods of life, when there is an absorption of fibrinous waste. Dr. Bennett places "hard work" among the causes of tubercle. In confirmation of this, all of the five thousand six hundred and twenty-seven persons affected with phthisis, as tabulated by Dr. Aitken, were working people.

"On the other side," says Rokitansky, "the pre-eminent immunity afforded by exquisite venosity and cyanosis, against fibrin-crases, more especially the higher (croupous) grades, and most particularly against tuberculous crasis—taking, we say, all these circumstances duly into account, we are forced on to the momentous conclusion that *arteriality*—that is, *the arterial development of fibrin—pre-eminently constitutes the cardinal character of tuberculosis.*" He says again: "There exists undeniably a habit, expressed in a delicate construction of the soft parts, in imperfect development of the muscular, with preponderance of the vascular, system, and in a so-called phthisical build of the thorax, commonly deemed ominous of pulmonary tubercle. It is essential, however, that this build should not, according to the vulgar notion, be imputed to the smallness of the lungs within a seemingly insufficient thorax, but rather to very voluminous lungs within a thorax the obvious narrowness of which, in its antero-posterior diameter, is amply compensated for by its length, with a relatively small abdominal cavity and small abdominal viscera."

Active muscular exertion induces an expansion of the breathing capacity, increased arterial circulation, and, consequently, increased arterial development of fibrin. This increase of fibrin finds a reservoir in the developed muscles, thus far filling the conditions most favorable to tubercle, which will obtain when there is a cessation, in some degree, from muscular exertion. This will cause a quantity of fibrin, when in the process of retrogressive metamorphosis, to be thrown into the blood-mass, and supplies the tubercular pabulum. This pabulum is supplied to the blood by whatever circumstance may cause the fibroid tissues to break down; and, as this obtains in inflammatory fevers and wasting disease, we have tubercle as a consequence.

In the habit, as just quoted, the delicate construction of the soft parts seems to be due to the accompanying preponderance of the vascular system, which retains, as it were, the fibrin, and thus prevents its assimilation, and the development of those tissues into which fibrin enters so largely; hence, "a delicate construction of the soft parts"; and the fibrin, instead of performing its proper function in the construction of tissue, is converted into tubercular matter.

3. The retrogressive metamorphosis of fibrin into tubercle, as well as in rheumatism, consists in oxidation. And the first results of this oxidation is the conversion of the sulphur and phosphorus of the fibrin into their respective acids. In this we have a sufficient explanation of two conditions which usually attend patients with incipient phthisis—viz., *first*, an acid condition of the system, especially of the digestive organs; *second*, an aversion to fatty ingesta. The latter is due to the fluids which emulsify the fats preparatory for digestion being rendered neutral or even becoming acidified instead of retaining their normal alkalinity. When the fibrin is freed of its sulphur and phosphorus, it must undergo further oxidation in order to become tuberculous matter. In this transmission the caseous matter assumes a taint just as fruit does when undergoing oxidation or rotting; and, as this taint is capable of being communicated to other and yet healthy fruit, so this tubercular taint is capable of being communicated to other and yet healthy fibrin.

This taint may find its origin in an individual from one of the following four causes: *First*, it may be transmitted from parent to offspring; this obtains when tubercle appears in the fœtus or in infancy; *second*, in cases of excessive lung capacity, and a preponderance of the *arterial* over the venous system—these conditions of the organism may be congenital, or acquired by following such pursuits as will increase the lung capacity; *third*, by local oxidation, as when phthisis pulmonalis follows fistula in ano, or tubercular inflammation of a joint—these form foci from whence tubercle is disseminated to other and distant parts of the body; *fourth*, by a healthy person inhaling the breath of a consumptive patient. This obtains by constant and intimate association of a healthy person with a consumptive patient.

In the latter case, it is reasonable to presume that the taint is carried by the micrococci of Koch. These microorganisms may be considered as a product, as mildew or fungus is the result of organic matter being exposed to oxidation.

4. The two diseases find a common remedy in those means which correct the hyperinosis. This proposition necessarily involves the treatment of the two diseases. As much of that which can be said of the one is alike applicable to the other, we will, for the present, speak of tubercle; and the treatment may be considered under two headings, viz.:

1. Preventive.
2. Curative.

In considering the preventive means, we are met on the threshold with a very pertinent question—viz., How are we to prevent hereditary phthisis? In answer to this, only a like pertinent response can be made, which is: If the parents can not be cured, then *forbid them bearing children.*

Aside from an inherited taint, an organism which is conducive to tubercle may be congenital—viz., large lung capacity and arterial predominance over the venous system. A person with such an organic construction should strenuously avoid vigorous exercise, and those circumstances and pursuits which occasion deep and prolonged inspirations. His diet should be of the carbohydrates; and as these belong, almost without exception, to the vegetable kingdom, and constitute the non-nitrogenous food, his diet should be vegetarian and not of meat. He should avoid the inhalation of an atmosphere laden with dust of any kind, as well as the breath of other people, inasmuch as this contains highly oxidized matter from the lungs. Such unwholesome atmospheres are found in crowded sleeping apartments, schools, and places where many people are assembled. But all the means of avoiding the inhalation of large quantities of air should be adopted. To this end the corset or moderate lacing is beneficial if not carried to such an extent as will interfere with the stomach and liver in the performance of their functions. Another and a most efficient means of lessening the amount of air taken into the lungs is to live in a warm climate. This constitutes the sole benefit that consumptives derive by going to Florida or other warm climates. There the atmosphere is rarefied by the higher temperature, so that less air is taken into the lungs at each inspiration. There are also two other circumstances to be met with which are important to the consumptive; viz., *first*, the higher temperature produces a lassitude which prevents so much exercise being taken—consequently less breathing; *second*, the diet consists more of fruits and vegetables and less of meats than in the more northern States; thus the fibrin is diminished. In this we find an ample solution of the problem involved in the rheumatic and consumptive patients declaring themselves greatly benefited by a winter spent in the Southern climes.

2. The curative treatment will involve a continuation of the preventive means as just enumerated. The next urgent matter to be considered is the acid state of the system which usually accompanies tuberculosis. A most efficient means of meeting this is the administration of one drachm of saccharated lime-water, and one grain each of hypophosphite of lime and of sodium, to be taken half an hour before each meal, dissolved in as much water as the patient can conveniently drink. The next important step is the correction of the taint. The means best adapted to this end lie in the use of the carbohydrates. The most prominent are alcohol and cod-liver oil. In order to obtain the greatest benefit from these, it is necessary to observe the condition under which they are administered. If the system is not freed from its acid condition, the oil can not be digested. And the object of administering the alcohol and oil would be defeated by advising the patient to take more exercise than is actually necessary, as it would be a great folly to give these agents to consume the oxygen and then direct the patient to inhale more oxygen by taking excessive exercise. In exercising, the patient should be as passive as possible—as in riding in a carriage or light horseback exercise. The use of alcohol and the oil will prove more efficient where the patient is strictly kept upon a pure vegetable diet. These agents act in preserving the fibrin from oxidizing in a manner similar to preserving fruit by keeping it free from the influence of oxygen; *i. e.*, by combining with the oxygen instead of the fibrin.

The parallelism of rheumatism and tubercle subsists in the hyperinosis and oxidation, and ceases with the latter. In rheumatism this consists in the oxidation extending only so far as the conversion of the phosphorus and sulphur into their respective acids; and not so far as to change or to rearrange the remaining elements of the fibrin into the form of caseous matter, but leaves it to pursue a more normal course in its metamorphic processes.

As the treatment of the two diseases in detail does not fall within the scope of this paper, it only remains to observe that, inasmuch as oil, alcohol, or a non-nitrogenous diet lessens the quantity of fibrin in the blood, the foregoing sufficiently demonstrates the proposition that drinking men, under ordinary circumstances, enjoy an immunity from rheumatism and tubercle.

Book Notices.

Manual of General Medicinal Technology, including Prescription-Writing. By Edward Curtis, A. M., M. D., Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons, etc. New York: William Wood & Co., 1883. 32mo, pp. viii–234.

Dr. Curtis has made a very systematic and useful little book and a very accurate one. The information it contains should be in every work on materia medica and therapeutics, and yet usually the subjects handled are very scantily treated of in such books. The technicalities of prescription-writing are discussed at considerable length. The naming of medicines, their forms, and the determination of the quantities of medicine to be used, are all carefully discussed. The methods of medication and dosage receive appropriate treatment. The questions of compatibilities of drugs, both chemically and physiologically, are also discussed. The book is for students, and is calculated as a reminder. The United States Pharmacopœia is followed, and the metric system is given a place.

Student's Manual of Electro-therapeutics. By R. W. Amidon, M. D., etc. New York: G. P. Putnam's Sons, 1884. Pp. v–93.

Dr. Amidon's book contains a very clear and straightforward account of the physical principles which underly electro-thera-

peutics. Indeed, we do not recollect having anywhere seen condensed in so concise and yet satisfactory a shape the laws governing electrical currents, and the facts regarding the physiological and pathological reactions of the human organism to electricity. The electro-therapeutical deductions from these facts are given very briefly and are mainly drawn from the author's personal experience, and are hence perhaps more valuable—certainly more authoritative—than if taken from hearsay or at second-hand.

The book is well adapted to its purpose—namely, to supply to the student of practical electro-therapeutics some elementary notions upon the subject; enough to enable him to employ a battery intelligently and understand the reactions which are involved.

Chemistry: Inorganic and Organic, with Experiments. By Charles Loudon Bloxam, Professor of Chemistry in King's College, London, etc. From the fifth and revised English edition. With two hundred and ninety-two illustrations. Philadelphia: Henry C. Lea's Son & Co., 1883. Pp. xxvii–33 to 738, inclusive.

This, the fifth, edition of Bloxam's well-known treatise has been subjected to careful revision, and the sections occupied with the principles and theory or *science* of chemistry have been brought "into harmony with modern views." The fundamental conceptions of chemistry relating to the constitution and properties of matter are amply and clearly, yet withal briefly, presented to the student in their most developed forms. Still, we miss any consideration of the import and relations of heat to molecular exchange, a growth of modern physics which promises to absorb the entire philosophy of chemical science.

As a practical treatise, responding to the demands of the medical student and working chemist, the present work will make secure the place won by previous editions.

BOOKS AND PAMPHLETS RECEIVED.

Outlines of Psychology, with Special Reference to the Theory of Education. A Text-book for Colleges. By James Sully, M. A., Examiner for the Moral Sciences Tripos in the University of Cambridge, etc. New York: D. Appleton & Co., 1885. Pp. xxiv–711.

A Text-book of Physiology. By M. Foster, M. A., M. D., F. R. S., etc. Third American, from the Fourth and Revised English Edition. By Edward T. Reichert, M. D., Demonstrator of Experimental Physiology in the University of Pennsylvania. With Two hundred and seventy-one Illustrations. Philadelphia: Lea Brothers & Co., 1885. Pp. 911.

Poisons: their Effects and Detection. A Manual for the Use of Analytical Chemists and Experts. With an Introductory Essay on the Growth of Modern Toxicology. By Alexander Wynter Blyth, M. R. C. S., F. C. S., etc. With Tables and Illustrations. Volume I. New York: William Wood & Co., 1885. Pp. xxxiv–333.

Tracheotomy in Laryngeal Diphtheria; After-treatment and Complications. By Robert William Parker, Surgeon to the East London Hospital for Children, etc. Second Edition, Revised and Considerably Enlarged. London: H. K. Lewis, 1885. Pp. xvi–124.

Medical Thoughts of Shakespeare. By B. Rush Field, M. D., Member of the Shakespeare Society of New York. Second Edition, Revised and Enlarged. Easton, Pa.: Andrews & Clifton, 1885. Pp. 86.

Lectures on Pulmonary Phthisis. By Ernest L. Shurly, M. D., etc. [Reprinted from the "Medical Age."]

NEW YORK, SATURDAY, AUGUST 15, 1885.

FERRÁN'S FIASCO.

It would be wrong to jump to the conclusion, from the utter collapse of Dr. Ferrán's vaunted procedure in the preventive inoculation of cholera, that inoculation may not yet be so carried out as to answer the purpose. But the tendency is a natural one to settle down into the stagnation of such a conclusion whenever a grand scheme of any sort is proved to be a bubble, and especially when, as in this instance, its promoter takes a position where he shows himself rather a seeker after pecuniary reward than a devotee of either science or humanity. It is of little consequence to the world when a person who has posed for a time as a great discoverer and a benefactor of the race drops to the level of a charlatan, except that the occurrence tends to create a disinclination on the part of competent and well-balanced men to enter upon a path which, whatever promise it might otherwise have seemed to hold out, has been in a certain sense defiled. To be sure, this feeling of aversion is always outgrown in time, but results that, but for its existence, would in all probability have been arrived at with rapidity are postponed many years, to the great detriment of progress.

If failure had been all that was to be chronicled of Dr. Ferrán's process, that in itself would not have brought him down to the station he now occupies in the eyes of the profession; he would simply have been set down as one who had generalized from insufficient data—a proceeding not unheard of in men who have nevertheless continued to enjoy the respect of their fellow-laborers, and even done subsequent solid service to science. Nor would his reserve—to use no harsher term—as to the details of his laboratory work, if indeed he has done anything worthy of the name, have aroused any special distrust, provided it had gone before his bold announcements. He might have been as silent as the tomb, and sported his oak like a miser, so long as his project was in that part of the experimental stage which ought unquestionably to have been worked out to the last detail before inoculations of human beings were resorted to as the final test: and it could not reasonably have been objected that he was straying from the legitimate course. But, when he appeared, so to speak, vaunting a perfected process with one breath and smothering investigation with the next, the weakness of his position was all but demonstrated.

It was natural, too, that he should look forward to a pecuniary reward when he had satisfied the world of his success. And under such circumstances, beyond all question, the recompense would have been forthcoming, and it would have been a handsome one. Jenner not only accepted, but took means to obtain, a substantial recognition of his great services to mankind,

and the fact has never dimmed the luster of his fame. His countrymen were glad and proud to afford him a tithe of the money that his discovery had saved, to say nothing of its other beneficent consequences, although the whole world gained by it as well as themselves. But Jenner worked patiently for years before he even announced his conclusions, and he countenanced no movement looking to a pecuniary recompense until all civilized communities had had the soundness of his doctrine and the utility of his practice demonstrated to them over and over again and on a large scale.

As matters stand, however, a practice abundantly shown to be well-nigh if not altogether useless, secrecy as to details—not for purposes of undisturbed study, but apparently only for mystification—and a hand held out after the manner of Artemus Ward's showman when he said to a would-be dead-head: "You can pay without going in, but you can't go in without paying"; all these features make the contrast sharp between Dr. Ferrán's case and that of any one of the world's few great discoverers. Let us hope that this very pointedness of the contrast may to a certain degree rob his fiasco of the retarding influence it might otherwise have had on researches in the preventive inoculation of cholera.

MINOR PARAGRAPHS.

ARTIFICIAL VIABILITY.

Perhaps this term may properly be applied to the results which seem capable of achievement by following certain devices that have been brought forward by the Paris obstetrician, M. Tarnier. Until lately, it was the practical difficulty of maintaining them at a uniform temperature of the required degree that made the survival of children born on the bare attainment of viability so decidedly improbable. M. Tarnier's success in doing away with this obstacle, by means of the *couveuse*, is well known to our readers. But this is not all. At a recent meeting of the *Académie de médecine*, as we learn from the "Progrès médical," M. Tarnier insisted upon the necessity of forced feeding (*gavage*). Through a urethral catheter passed into the stomach, and provided with a glass funnel at its free end, a nutritive liquid is to be poured, preferably human milk. In the case of very young infants, two drachms of milk are injected every hour, and, after a time, the breast is given in alternation with these injections. The cautions are mentioned that the catheter should be withdrawn rapidly after the milk has reached the stomach, and that care should be taken not to throw in too much at any one time. By resorting to these expedients, it is thought, children born so early as the sixth month may be reared.

A FRENCH VIEW OF THE AMERICAN TRADE PROPENSITY.

"Lyon médical" has noticed an advertisement of an American device termed a "menstrual receptacle," and, under the caption "On s'arrêtera l'industrialisme américain?" remarks that the advertiser has devised a little cup which, embracing the cervix uteri, is intended to receive the catamenial dew without the loss of a drop. The dimensions of the shank which supports the cup give rise to reflections, says our contemporary, the first of which is, that it is surely impossible to push progress farther—or deeper.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 11, 1885:

DISEASES.	Week ending Aug. 4.		Week ending Aug. 11.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	27	5	14	4
Scarlet fever	23	4	8	2
Cerebro-spinal meningitis	2	2	2	1
Measles	21	4	16	2
Diphtheria	33	17	20	14
Small-pox	2	0	1	0

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, August 4th. *Acapulco, Mexico.*—For the week ending July 19th: Free from epidemic diseases. *Cape Haytien, Hayti.*—For the week ending July 25th: Free from epidemic diseases. *Cardenas, Cuba*, and *Laguayra, Venezuela.*—For the week ending July 25th: Free from epidemic diseases. *Callao, Peru.*—For the week ending July 4th: One death from yellow fever and one from small-pox. Fever reported as declining in the town. Small-pox prevailing very generally among the lower classes. *London, England.*—For the week ending July 20th: 118 cases of small-pox admitted to hospital during the week; 15 deaths reported. Total number of cases in hospital at the end of the week, 782; deaths from diarrhœa and dysentery, 210, and from simple cholera, 4. *Paris, France.*—For the week ending July 25th: No cholera or small-pox reported. *Nice, France.*—For the two weeks ending July 15th: Free from small-pox and cholera. *Barcelona, Spain.*—By cable, August 4th, the consul reports cholera present, but not officially declared. *Denia, Spain.*—July 28th: Cholera officially declared; there are from 3 to 6 deaths daily. *Gibraltar, Spain.*—August 9th: 1 death from cholera at the civil hospital. *Malaga, Spain.*—August 7th, the consul reported 4 cases of cholera; on the 11th the civil authorities announced that the cases reported on the 7th were not cholera. *Genoa, Italy.*—For the week ending July 12th: Free from epidemic diseases. *Venice, Italy.*—For the week ending July 11th: 2 deaths from small-pox. *St. Petersburg, Russia.*—For the week ending July 18th: 3 deaths from small-pox. The presence of yellow fever at *Vera Cruz, Mexico*, has been announced by telegram from the consul, but no further information has yet been received.

The Mount Sinai Hospital Training-School.—We learn that Miss P. B. Washburne, the principal of the school, has resigned, and that Miss A. F. Jones, who lately resigned the position of superintendent of nurses at the Charleston, S. C., City Hospital, is to succeed her. Both ladies are graduates of the New York Hospital Training-School.

Medical Department of Yale College.—It is reported that Dr. F. E. Beckwith has resigned the chair of Obstetrics and Diseases of Women and Children.

Carney Hospital, South Boston, Mass.—Dr. William A. Dunn has been appointed visiting surgeon, and Dr. G. H. Monks and Dr. H. W. Cushing have been appointed surgeons, to the out-patient department.

The Illinois Register of Physicians and Midwives.—The Illinois State Board of Health gives notice that it is now engaged in revising the "Register," and that it will regard any notification of changes, omissions, or errors as a favor. Corre-

spondents should address: "The Secretary of the State Board of Health, Springfield, Ill."

The Death of Dr. George A. Bates, of Worcester, Mass., occurred suddenly on Saturday, August 8th, in his sixty-fifth year. He was graduated from Harvard Medical School in 1844, and the greater portion of his professional life was spent in Worcester. He was a member of the Massachusetts Medical Society.

The Death of Dr. Joseph R. Draper, of South Boston, Mass., took place on Wednesday, August 5th, in his fifty-fifth year. He was a native of Wayland, Mass., and was graduated from Berkshire Medical School in 1863. He was a member of the Suffolk District, and of the Massachusetts Medical Societies.

The Death of Dr. William Wood, of East Windsor, Conn., took place on Sunday, August 9th, at the age of sixty-three. He was a native of Waterbury, Conn., and was graduated from the Medical Department of the University of the City of New York in 1847. He was a member of the Hartford County, Conn., Medical Society, the Lyceum of Natural History of Williams College, and a corresponding member of the Nuttall Ornithological Club of Cambridge, Mass., and was a recognized authority in ornithology.

The Death of Dr. Thomas B. Jewett, of Birmingham, Conn., took place on Sunday, August 9th, in his thirty-seventh year. He was a son of the late Dr. Pliny A. Jewett, of New Haven, and was graduated from the Medical Department of Yale College in 1879.

The Death of Professor Milne Edwards is announced in the "Gazette hebdomadaire de médecine et de chirurgie." He had reached the age of eighty-five years, and had been a teacher for many years. At the time of his death he was a member of the *Académie des sciences* and of the *Académie de médecine*, honorary dean of and professor of comparative physiology in the *Faculté des sciences*, and professor at the Museum of Natural History. Early in his career he made numerous contributions to practical medicine, but the greater part of his life was devoted to physiology.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 2, 1885, to August 7, 1885:*

Brown, J. M., Surgeon; Ewen, Clarence, and Taylor, A. W., Assistant Surgeons. Ordered to rejoin their proper stations in the Department of the Platte. G. O. 7, Division of the Missouri, August 1, 1885.

Edie, G. L., and Black, C. S., Assistant Surgeons. Ordered to rejoin their proper stations in the Department of Texas. G. O. 7, Division of the Missouri, August 1, 1885.

Powell, J. L., Captain and Assistant Surgeon. Assigned to temporary duty at Fort Leavenworth, Kansas. S. O. 110, Department of the Missouri, July 30, 1885.

Dietz, William D., First Lieutenant and Assistant Surgeon. Ordered from Fort Selden to Fort Stanton, New Mexico. S. O. 111, Department of the Missouri, July 31, 1885.

Society Meetings for the Coming Week:

Monday, *August 17th:* Hartford City, Conn., Medical Association; Chicago Medical Society.

Tuesday, *August 18th:* Medical Society of the County of Kings, N. Y.; Ogdensburg, N. Y., Medical Association.

Wednesday, *August 19th:* New Jersey Academy of Medicine (Newark).

Thursday, *August 20th:* New Bedford, Mass., Society for Medical Improvement (private).

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of May 21, 1885.

The President, Dr. A. Jacobi, in the Chair.

Observations on the Treatment, Medical and Surgical, of Acute Peritonitis.—Dr. T. H. Burchard read a paper on this subject. [See p. 169.]

Dr. A. L. Loomis did not believe in idiopathic peritonitis; for five or six years he had searched diligently at autopsies for a case in which no local or constitutional cause of the peritonitis could be recognized, but he had found none. As the author had stated, we could group all cases under three heads—those in which the cause was constitutional and dependent upon blood poisoning, those arising from extension of inflammation from neighboring parts, and those dependent upon perforation or rupture of some form. He had yet to see a case of peritonitis end in recovery in which there had been unmistakably an escape of intestinal gases into the peritoneal cavity. He recognized the escape of the intestinal contents into the peritoneal cavity as one of the most fatal of accidents. It was not always possible to determine just what part of the gut was involved, even in cases in which the symptoms were localized, for previous adhesions, etc., might have caused a displacement of the several portions of the intestine. But, if the commencing point of peritoneal inflammation could be determined exactly, he would most heartily indorse all that had been said in favor of laparotomy. He had seen more than one such case. Where there was perforation of the vermiform appendix there often existed localized peritonitis, with fixed pain, increased on firm pressure, arrest of abdominal respiration, and feebleness of heart power which did not correspond to the amount of pain or the apparent gravity of the disease. When such symptoms came on rapidly or suddenly, he thought we were justified in resorting to surgery, or, if the symptoms did not yet point positively to perforation, the physician should stand by his patient prepared to perform the operation when the first signs of perforation should appear. He had on several occasions pointed out to surgeons the indications for the use of the knife in acute peritonitis. Experience had shown that the peritonæum was not such a dangerous membrane to invade as it had formerly been regarded. If, however, general peritonitis had developed, with shock and collapse, the pulse at 160, and the respirations altogether thoracic, an operation offered but little chance of success. It was in the early stage that the operation should be done, to give the best chance of recovery. He believed thoroughly in the opium treatment of peritonitis, but with restrictions, such as had been pointed out in the paper. For a long time he had guarded his first doses of opium with atropine; later on in the disease it was not so necessary to combine atropine with the opium.

Dr. R. F. Weir thought that during the past ten or fifteen years surgeons had taken a long stride in advance in the treatment of diseases and injuries of the abdomen, especially the latter. Dr. Loomis, he thought, had struck the key-note when he stated that there was no such thing as idiopathic peritonitis. In no case of peritonitis should the patient be allowed to die without receiving the benefit of an exploratory operation. He agreed with Treeves that there was no mesocolon which led to connective tissue behind the peritonæum; perforations always took place inside the peritoneal cavity. He called attention to the importance of earlier interference in so-called perityphlitic abscess; surgeons should not wait until they were able to withdraw pus with the aspirator-needle before cutting down and

establishing drainage. In traumatic cases it was difficult to determine whether the patient was simply in a state of collapse, whether there was escape of the intestinal contents, or whether there was hæmorrhage. But the comparative safety of exploratory incision of the abdominal cavity justified us in such cases in opening the peritonæum. He referred to the success of two operations under such circumstances, one being performed by Mikulicz and the other by Kocher. He was entirely in accord with the author of the paper as to the importance of an early operation.

The PRESIDENT said it was a question with general practitioners whether in every case of perityphlitis an early operation should be resorted to. He believed that we were not all fully prepared to operate at once, even though the diagnosis might be satisfactorily made, and for the reason that in a large number of cases the local inflammation did not extend. We knew of recoveries, too, in cases in which a perityphlitis had become a general peritonitis. For the general practitioner, it certainly was a responsible position to decide the question whether or not an operation should be done at once, or whether we should wait for some time. He had met with just such a case within the last two weeks, that of a boy fifteen years of age who gave a history of perityphlitis—sudden pain, local swelling in the right inguinal region, some dullness on percussion, slight elevation of the thigh, a moderate amount of fever, and absence of collapse. In such a case, then, the question would be raised, Should an operation be performed at once? The patient was given morphine with atropine, and they applied ice, ice, ice! The peritonitis became general, but the symptoms were not urgent; the temperature rose above 103° only once; there was pain over the abdomen, with thoracic respiration. He hesitated to recommend an operation, because the general condition of the patient seemed to justify a little more waiting. If in such a case death should occur, perhaps the physician might be reproached with not having proposed an operation. He heartily agreed with the statement that there were hardly any cases of idiopathic peritonitis. He was not prepared to say, even after hearing this paper and the discussion, that he would at once propose laparotomy in the class of cases mentioned, but he would propose it if peritonitis had set in suddenly after an attack of perityphlitis, and extended very fast. Dr. Loomis had said, Operate when the first sign of perforation makes its appearance; but perforation was frequently the first thing which occurred.

Dr. LOOMIS thought he had said that the surgeon should be prepared to operate in all of these cases as soon as the evidences of perforation became known. He would beg to question the statement that perforation was the beginning of a perityphlitis. He mentioned a case in which he saw the patient on a Thursday, when there were localized symptoms in the right iliac region, not severe, but the facies pointed to some serious trouble. On Friday the patient felt well and got up, but on Saturday there was sudden collapse, and death occurred with general peritonitis. Autopsy showed lymph about the local trouble, of two or three days' formation, and evidence of subsequent perforation and general peritonitis. Had an operation been done at first, the patient might have recovered.

Dr. WEIR remarked that in speaking of an early operation he did not mean that it was necessary to resort to laparotomy, but to the ordinary operation for perityphlitis, with the insertion of a drainage-tube.

Dr. LOOMIS had stated at the beginning of his remarks that there was no cause of peritonitis which was so fatal as the escape of the intestinal gases into the peritoneal cavity. He could understand how the vermiform appendix might be plugged at its opening into the intestine, and ulcerations occur farther on which might set up an inflammation in the connective tissue, give rise to hardening, etc., and recovery finally take place; but, when the ulceration was situated near enough to the intestine to cause an escape of the intestinal gases, he could not see how it would be possible for the patient to escape acute general peritonitis.

Dr. BURCHARD, in closing the discussion, said he had seen six cases of perityphlitis attended by perforation, in five of which he made a post-mortem examination and verified the diagnosis. It was a peculiar fact in these cases, and was commonly true, as had been pointed out in the discussion, that prior to the perforation which caused death there had been one or more attacks of perityphlitis, and that he considered a very strong diagnostic mark. If we found a patient in complete or partial collapse who had had preceding perityphlitis, he thought we were justified in concluding that there was perforation, and particularly if there had been previous constipation and the patient had been taking an active purge. If there was but very little collapse, he thought we were justified in concluding that, if there was perforation at all, it was so minute that it could not be diagnosticated. If the collapse was profound, as it was in most cases, and developed rapidly, we were justified in inferring that there was perforation.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Meeting of June 11, 1885.

The President, Dr. E. O. SHAKESPEARE, in the Chair.

The Relative Malignancy of Different Forms of Sarcoma.—Dr. H. R. WHARTON presented a large tumor which had been removed from the posterior portion of the thigh of a patient in the University Hospital, under the care of Dr. Ashhurst. The patient was a man, thirty-two years old, who, some eight years ago, had first noticed a small tumor of the posterior portion of the left thigh, about six inches above the popliteal region. Since that time it had gradually increased in size, and at the time of his admission it was larger than a man's head and oblong in shape. Its growth had been accompanied by paroxysmal attacks of severe pain. The patient did not remember any injury of the part. The tumor was enucleated without difficulty, laying bare about six inches of the sciatic nerve, which was directly in contact with the capsule of the tumor, over which also portions of the semi-tendinosus and biceps muscles were stretched. The tumor was found to consist of one large cavity containing a reddish-brown fluid, surrounded by a fibrous wall varying in thickness from an inch to two inches, and in places presenting numerous points of calcareous degeneration. The inner surface of this wall was lined with irregular flocculent masses. Microscopical examination showed the growth to be a spindle-celled sarcoma with scattered areas of calcareous degeneration. The chief points of interest in the case were the large size of the tumor, its slow development, and the ease with which it was removed without injury to adjacent structures.

Dr. TYSON thought it would be interesting to determine if this cyst—which was a typical example of cyst-formation by softening—had an endothelial lining. He also asked as to the nature of the liquid contents.

Dr. DE SCHWEINITZ replied that he had been foiled in his efforts to make satisfactory sections, from lack of time to decalcify the growth. He had determined, however, that it was unquestionably a spindle-celled sarcoma. The contents of the cyst had been spilled during the operation; they were of a chocolate color.

Dr. BARTON said that at the previous meeting Dr. Nancrede

had shown two growths with a similar clinical history and of analogous histological characters. It would be interesting to examine both growths with reference to the state of the walls of the blood-vessels, as suggested by Dr. Nancrede, to ascertain if any light could be thrown on the question of the non-malignancy of the so-called recurrent fibroid tumor of Paget.

Dr. Nanorede remarked that at the previous meeting he had specially called attention to the fact that the *so-called* recurrent fibroid of Paget was a small-spindle-celled sarcoma. The position which such growths occupied—viz., in the subcutaneous connective tissue—did not seem to him, as had been suggested by Dr. Simes, a satisfactory explanation of their non-recurrence. He was under the impression that a careful study of the histology of their vessel-walls would demonstrate that they more closely resembled those of a fibroid tumor than those of other sarcomata in not being merely channels through the tissue, directly or almost directly in contact with the tumor-cells. He thought that "recurrent fibroid" was a good clinical term, as applied to a certain class of sarcomata, since other tumors much resembling them in histological character pursued a far different course.

Dr. Tyson said that he had early made a study of the growth first known as the fibro-plastic tumor of Lebert, and afterward named by Paget recurrent fibroid, but now correctly included among the sarcomata of Virchow. He thought that the explanation of its non-malignancy was to be found in the fact that the physiology of sarcomata varied greatly in this respect, some being scarcely more malignant than certain fibromata, while others vied with the worst cancers in this characteristic. The former were represented by the hardest of the sarcomata, which, again, were the small-spindle-celled growths and might be said to be the type of the recurrent fibroid of Paget. He agreed with Dr. Nancrede that the term was a good one clinically, designating a small-spindle-celled sarcoma recurring *in loco*, but seldom by metastasis.

Dr. Formad said that no true tumor ever had arteries or veins; their blood-vessels were merely blood-channels without muscular walls, even in fatty tumors. The cancers were an exception to this; they had true blood-vessels and nerves, and hence were painful.

Dr. Nanorede replied that, as Dr. Formad's statements were totally at variance with those of all reliable observers, he was not prepared to accept them at present, and still thought that careful study of the histology of the vessel-walls in the various sarcomata might reveal something of practical interest.

Dr. Formad said that, to him, the relative non-malignancy of these growths was plain; spindle cells could never move from their position, especially if the blood-vessels were small. The small-round-celled sarcomata had small cells and were more vascular; hence they were very malignant by metastasis. Giant-cells never traveled.

The President remarked that the suggestions of Dr. Nancrede and Dr. Barton, as to a possible difference in the blood-vessel walls of sarcomata of differing malignancy, were doubtless based upon the well-known fact that these growths became generalized through the blood-channels. This seemed to him a matter of interest, and it also raised a point which might be found of importance, if properly investigated, as explaining the clinical differences. It was indeed true that the tendency to malignancy by metastasis was due in large part to the ease with which cells could be detached from their place, and this had as much to do with metastasis as the supposed mobility of elements. As to the condition of the vessel-walls in recurrent fibroma, he was very sure that, in the primary tumors which had been diagnosticated, after removal, as pure fibromata with numerous endothelial cells along the bands of fibrous tissue, recurrences had shown a change of type to that of perfect sarcomata; yet the blood-vessels in the first were those of connective tissue, while in the second they had the character of simple blood-channels.

Dr. Hughes would call attention to a theory of a recent German observer, that all sarcomata arose from the endothelia of blood-vessels. On that supposition it could easily be understood how they became generalized; these cells set up the same change in the endothelia wherever they touched them, while cells derived from other structures had no effect. This distinction might be made between sarcomata that remained local and those that became generalized—that the former arose from fibrous tissue, and not from endothelium.

Dr. Nancrede was of course perfectly familiar with the fact that mobility of cells had much to do with malignancy, but he felt compelled to deny positively, upon the basis of experience, the so-called fact, so positively asserted by Dr. Formad, that large-spindle-celled sarcomata never could become generalized, because their cells, from their form, must "stick" in the vessels. Some years since he had presented to the society a specimen of the most malignant growth he had ever had the misfortune to deal with. (Here he repeated its history.) He thought that Dr. Formad had examined that specimen at the time, and had not then dissented from his opinion. He would relate other instances presented to this society, but further remark was unnecessary, since all observers except Dr. Formad had repeatedly called attention to the special malignancy of large-spindle-celled sarcomata, save in certain situations. He would suggest that positive statements founded on any one observer's experience were apt to be delusive.

Specimens from an interesting case of pneumonia in a child, with extensive consolidation, were shown by Dr. M. H. Fussell, and Dr. G. de Schweinitz showed two specimens of sarcoma of the choroid.

Reports on the Progress of Medicine.

OBSTETRICS.

By ANDREW F. CURRIER, M. D.

The Influence of Temperature upon the Life of the Fœtus, and upon the Progress of Gestation.—Doré ("Arch. de tocol.") has made three series of experiments upon animals bearing upon this subject. He compares these and their results with similar investigations which were made by Runge, with whom he disagrees in most respects. His conclusions are as follows: 1. The first conclusion of Runge can not, with our present knowledge, be refuted—namely, that the temperature of the fœtus is always higher by some tenths of a degree than that of the mother even when the latter is above the normal. 2. No well-conducted experiment has ever proved that the fœtus dies a long time before the mother. [Presupposing that the mother is in a dying condition, from whatever cause.] When the mothers were opened after death the fœtuses were invariably found dead, but when this operation was performed before death, even though the mothers were *in extremis*, the fœtuses were found alive. 3. A temperature of 41·5° C. is not always lethal for the fœtus. Runge thinks that when maintained at this point for a few minutes it is necessarily fatal. The author's experiments showed that it might in some cases be continued for two hours without producing death. 4. A temperature of 43° C., if arrived at by slow and cautious elevation, may be endured for a short period without interrupting the pregnancy or affecting the vitality of the fœtus. 5. Excessive elevation of temperature *alone* is insufficient to produce abortion or premature parturition. In all of the author's experiments, whether the mother succumbed to the heat or successfully

resisted it, this proposition was sustained. 6. There is great difference, even with animals of the same species, in the normal temperature point and in the rapidity with which hyperpyrexia is acquired, the same rate of increase of external heat being observed in all cases.

The Influence of Age upon Labor in Primiparæ.—Kleinwächter ("Ztschr. f. Geburtsh. u. Gynäk."), after analyzing the statistics of nine hundred and twenty primiparous cases, which were recorded at the Innsbruck clinic, the patients varying in age from sixteen to forty-one years, draws the following conclusions: 1. As a rule, the greater the age at which conception occurs for the first time, the older the individual when menstruation began. 2. The reason of this is to be found, at any rate in part, in precedent disturbances in the ovulation process. 3. Pain occurring either with the first menstruation, or in a subsequent one soon after it, among those who begin to menstrute at a period which is later than the usual one; likewise irregular menstruation, and pain during coitus, which renders that act imperfect, are causes which tend to retard the period when conception first occurs. These factors are most potent in women of an advanced stage of life, less so in those who are midway in the child-bearing epoch, and least among very young women. 4. Pathological conditions which have no immediate relations with the pregnant state interfere with conception least frequently in young women, but very commonly in older ones. 5. The pain and annoyance attending the pregnant state are most common with very mature primiparæ, and less common with primiparæ of the middle than of the earliest stage. 6. Hæmorrhages during pregnancy occur most commonly among the young, least commonly among the old. 7. As to an increase in the quantity of liquor amnii, age does not seem to be a determining factor. 8. The duration of labor is most frequently prolonged beyond the normal time among old primiparæ. 9. Inexpulsive and ineffective pains are most common among primiparæ of the latest period. 10. The forceps is most frequently called for with those primiparæ who are more than twenty-nine years of age. 11. Though the duration of labor is longer with old primiparæ than with young ones, it does not follow that this is an inevitable and unvarying fact. 12. (This proposition simply qualifies its predecessor.) 13. The percentage of mortality in primiparæ following forceps operations increases in the same ratio with the age. 14. The older the primipara, the more likely is the perinæum to be torn. 15. The older the primipara, the greater the probability that post-partum hæmorrhage will occur. 16. Increase of age brings increased predisposition to kidney troubles. 17. The same rule applies in regard to œdema. 18. The older the primipara, the less the probability that she will suffer with inflammation of the breasts, or that she will be able to nurse her child. 19. Old primiparæ are most frequently the subjects of puerperal fever; least frequently affected are those who are between twenty and twenty-nine years of age. 20. The same rule holds in regard to puerperal mania. 21. Equally true is it in regard to morbidity and mortality with reference to puerperal diseases in general. 22. The same rule obtains in regard to spontaneous abortions; the older ones are most frequently the sufferers. 23. Abnormal presentations are most frequent with old primiparæ. 24. As to the narrow or deformed pelvis, age has no bearing upon the question. 25. The older the primipara, the greater the probability that the offspring will be a boy. 26. The children of old primiparæ are apt to be heavier and longer than those of young ones. 27. The older the primipara, the more likely is she to give birth to twins. 28. The same is true in regard to deformed offspring. 29. Also the rule applies in regard to the vitality of the offspring.

The Treatment of the Perinæum in Pregnant and Parturient Women.—W. A. Duncan ("Lancet") shows that an operation upon a ruptured perinæum is not necessarily an efficient cause of abortion in a pregnant woman by the narration of a case in which it was performed upon a woman in the third month of pregnancy. She had already borne two children, and the perinæum had been ruptured at each labor. The rent had been closed after the first accident, but not after the second, until the operation was performed by the author nine months after labor. Four deep wire sutures were used, and a sufficient number of superficial catgut ones. The operation was entirely successful, pregnancy was completed, and no accident occurred at the subsequent labor. In regard to supporting the perinæum during labor, the author thinks that the plan is sometimes a very good one, though accidents will sometimes happen in spite of all precautions. The plan which is recommended is to dilate the perinæum with the fingers closed in the form of a cone, and applied carefully when the head has reached the perinæum. He also approves of the plan of lateral incisions of a rigid perinæum, and thinks that the forceps, properly used, will prevent rather than encourage perineal rupture, on account of the dilating action of the blades. The supporting power of the perinæum to the pelvic organs is considered to be too important a matter, as regards the comfort and welfare of parturient women, to be overlooked or lightly regarded.

The Treatment of Placenta Prævia.—Murphy ("Brit. Med. Jour.") reports fifteen cases of this complication, in all of which the mothers recovered, recovery being delayed in one case, however, by an attack of phlegmasia dolens. Five of the children were born alive, but three only survived, and four of the others were dead when the patient was first seen. In regard to the causes which produce hæmorrhage (ante partum) in cases of placenta prævia, the author follows Matthews Duncan in considering that they may be (1) rupture of a utero-placental vessel, (2) rupture of a marginal utero-placental sinus, (3) partial separation of the placenta from accidental causes, as a jerk or a fall, (4) uterine pains from attempted miscarriage which is arrested at an early stage. Müller is quoted as stating that hæmorrhage is most frequent in cases of complete placental presentation between the twenty-eighth and thirty-sixth weeks; in the incomplete forms it usually comes after the thirty-second week. After such a warning as is given by hæmorrhage at this period, the sooner labor is induced the better the chances for both mother and child. The operation which will be required is the same in principle, whether labor has begun or not, and the author is very decided in his opinion that the vaginal tampon is *not* the means which is required. Immediate dilatation of the os is the end which is to be attained. Tents or the finger may first be used, and then Barnes's hydrostatic bags, or Steele's modification of the same. After a moderate degree of dilatation has been effected the finger should be passed into the uterus, and should separate all the placenta which is contiguous to the os internum. If uterine pains occur, the hæmorrhage will cease, the theory being that the vessels in the detached portion of placenta contract with the contractions of the uterus, and do not drag upon the vessels which are still intact as they did before the placental separation was effected. If hæmorrhage does not cease, ergot should be given. Dilatation being accomplished, the case may be left to nature. Rapid delivery may be effected with the forceps, but in the majority of cases version will be the most appropriate operation.

Defective Lactation.—Dolan (*Ibid.*) cites the following general principles upon this subject: 1. All therapeutical agents intended to act on the mammary gland must first enter the blood, or be capable of stimulating the blood supply in the mammary apparatus, the principle being that nutrition is dependent on blood supply. 2. Drugs from the families *Liliaceæ*, *Cruciferæ*, *Solanaceæ*, *Umbelliferæ*, etc., enter the blood and impregnate the milk, so that poisons in any of these classes must be administered with caution to the mother or nurse. 3. There is no true galactagogue, but jaborandi is the nearest approach to one. Its action is not persistent, however, and it affects the mammary secretion only temporarily. 4. Belladonna is an antigalactagogue. 5. In inaction of the mammæ the milk may be increased and influenced by medicines. 6. The salts of milk may be improved, as to quantity, by the action of medicines. 7. Various physiological actions, purgative, alterative, diuretic, etc., may be produced in the child by the administration of drugs to the mother. 8. Diet and hygiene must be regarded in order to effect improvement in the milk-secreting power. In regard to the causes of defective lactation: 1. They may be mechanical (*a*) through non-development of the lactiferous tubes; (*b*) through non-development of the cæcal terminations of the ducts; (*c*) through non-perfection of epithelium. These conditions can not be remedied. Plethora can be remedied by suitable, non-stimulating, nutritious diet. 2. Torpor of the mammæ may be overcome by repeated applications of the electric current, by irritation of the nipple, warm poultices, and the breast pump. 3. The commonest cause of defective lactation is anæmia, which is associated with constitutional degeneration. This radical defect is shown to be a very common condition, especially among the overworked and underfed laboring population in manufacturing communities. A degeneracy of the race, at least in so far as these classes

are concerned, is steadily progressing. One great remedy which is suggested consists in counteracting the vice of intemperance. The number of places of refreshment and entertainment for the poor should be greatly increased, and coffee, cocoa, tea, milk, soup, vegetables, etc., be furnished at low prices, the object being to displace with establishments of this character the present evil system of public-houses and dram-shops. The best mothers and the least amount of degeneracy are, says the author, in the middle classes. Woman's mission must ever be regarded in its association with motherhood, for the accomplishment of which important evolutional and nutritive changes must be undergone. If the forces which are involved in the process of reproduction are weakened, the result is necessarily a weakening of the race. Therefore the necessity of surrounding the function of lactation with proper safeguards can not be overestimated.

Miscellany.

The International Medical Congress.—Dr. D. Bryson Delavan, of New York, authorizes us to announce that he has declined to take part in the Congress as at present organized. The "Medical News" announces the withdrawals of Dr. Hunter McGuire, Dr. S. P. Moore, and Dr. James B. McCaw, of Richmond; Dr. Le Grand N. Denslow, of St. Paul; Dr. John L. Atlee, of Lancaster; and Dr. Joseph R. Smith, of the army.

The situation continues to be made the subject of comment by several of our contemporaries. The "Kansas City Medical Record" says: "In the June number of the 'Record' we partly gave way to our feelings regarding the outrageous action of a few supercilious nabobs, who have nothing to lose by any disturbance created in the medical profession. In our article we suppressed much of our disgust, with the hope that all dissatisfaction might be peacefully settled, and the profession appear as a unit in trying to make the international meeting what it should be—a well-merited credit to the American medical profession. It now seems that we are to be sadly disappointed in this our wish.

"The new committee appointed at New Orleans met at Chicago about the end of last month. A few members of the original committee met with them, but, of course, being in a hopeless minority, were forced to submit, which they did with apparent grace. Dr. Austin Flint, Sr., chairman of the original committee, sent in his resignation, which was quickly accepted. This showed the direction of the wind, which has nearly destroyed the Congress.

"Dr. Flint did the correct thing in resigning, as he was not the chairman of the new committee; but the committee did a very unwise thing in accepting the resignation. This first act of the committee was a direct blow at the original committee. The leading physicians of Philadelphia led off in their unqualified condemnation of the action taken at the Chicago meeting, and were soon followed by the profession of Boston, Baltimore, and other places. We are sorry to see this growing dissatisfaction, which, if it continue, will ruin the Ninth International Medical Congress. It may be noticed that the men whose names appear among the disaffected in the different organizations are the recognized leading members of the profession, who have always occupied a front rank in medical association meetings. Hence, with these men withdrawing from the committees, it looks very cloudy for the Washington meeting in 1887."

The "Columbus Medical Journal" says: "The fear that we expressed a couple of months ago bids fair to be realized; the Texas kick has 'overturned the fat into the fire.' In other words, the officers of the Congress, as selected by the new committee, are very generally refusing to serve; at least, such is the case with those from Philadelphia, Boston, Washington, Cincinnati, and Baltimore, while numerous other resignations have come in from other cities. Many of the most important sections have thus been left without officers. Five of the original committee of eight have resigned, including Dr. Billings, and the secretary general has also declined to serve. Matters have, indeed, assumed such a shape that no one with any self-respect can afford to take the places thus left vacant. To be a *second choice*, even under the most favorable circumstances, is always sufficiently humiliating; but to consent to be such in the present crisis would certainly indicate an utter absence of professional pride. We are told of three London tailors who once met and 'Resolved, that we, the people of England,' do thus and so. It now looks as though about the same number of 'kickers' would gather themselves at Washington, two years hence, and call themselves an International Congress."

. . . . . .

"The cry against the 'new-code' men was all bosh. It was raised at New Orleans simply to divert attention from the real purpose of those who uttered it, on precisely the same principle as the matador flaunts his red flag in the face of the bull. A few sharp and unscrupulous politicians—who had no claim to recognition in the organization of the Congress, and had hence received none—used that cry as a means of foisting themselves into prominence. They succeeded in their *ruse*, but 'vaulting ambition o'erleaped itself,' and the Congress, under their management, is hopelessly fated. They have come to a realizing sense of this fact, and, anxious to stand from under, are now wildly endeavoring to make themselves, and others, believe that the blame for the failure must rest on those who have withdrawn! They may deceive themselves by such audacious claims, but surely no one else."

The "Medical Record" publishes an open letter addressed to Dr. John V. Shoemaker by Dr. Henry D. Noyes, of New York, from which we extract the following: "With the excisions and withdrawals of our ophthalmologists and of other medical men can we still offer inducements powerful enough to bring to us the men we want from Europe? Can I explain to my *confrères* in Germany, Switzerland, Paris, and London, who expressed their intention of coming and who loaded me with hospitalities—can I account for these withdrawals and exclusions in any way which will not bring disgrace upon our medical profession?

"The situation is profoundly critical, and failure is certain unless an absolute reversal of the present policy is quickly effected. The delegate idea must be abolished. The pledges given at Copenhagen must be carried out in good faith to the letter. This means that men who have been treated with indignity must be invited back. To do this is not pleasant to human nature, but it is manly, and it is imperative. The Congress must be free to all physicians of honorable standing. Better to have a sprinkling of unworthy men, or of irregulars, than to persist in the mischievous and suicidal course now causing disintegration. Nor can we long delay. To wait until next May is to multiply difficulties and aggravate evils. The officers of the American Medical Association and the new committee should take the responsibility of such measures as will be radical enough to restore confidence, to bring back harmony, and to counteract the distrust which will spread through Europe most rapidly and be counteracted very slowly."

The "Virginia Medical Monthly" says:

"We are not surprised, and must confess being glad, at seeing with what almost unanimous action on the part of the leading members of the profession the result of the Chicago session of the newly appointed committee has been met. The resignation of nearly every prominent appointee on the full committees and sections made at that session shows a feeling of dignity and self-respect; and the fact that so many physicians in different parts of the country have expressed their sympathy with that action is plainly indicative of a feeling that something is more than wrong in the position taken by the American Medical Association at its late meeting in New Orleans. The thing to be sorry for is not the fact of these meetings in different cities and the action there taken by the doctors present, but the fact that all this was made a necessity by the personal ambition of some men who felt that they had been slighted.

"The medical press of England has already referred in no complimentary terms to this last-mentioned subject, and the action of the association has not tended to increase the respect of our professional brethren across the water.

"It is most certain that, unless some new action is taken in reference to the committee formation, the Congress will be a failure—a thing which must not be allowed to occur, and, although we acknowledge the shortness of the time which will elapse between the 1886 meeting of

the American Medical Association and the 1887 meeting of the International Medical Congress, it seems to us the only thing now to do is at the next association meeting to wipe out by carefnl legislation all existing committees, and appoint an entirely new one—not on the narrow basis of a printed set of rnles rapidly becoming obsolete by the advance of thought and charity—but on the broad platform of fraternity, honesty of purpose, and dignity."

The "Medical News" publishes the following preambles and resolution, adopted by the Dallas County (Texas) Medical Soeiety, at a special meeting held July 25th:

"*Whereas*, The American Medical Association, at its meeting in Washington city, in May, 1884, recognized a general desire of the medical profession of the United States by adopting a resolution under which a committee was appointed whose duty it should be to extend an invitation to the International Medical Congress, shortly to assemble at Copenhagen, to hold its next meeting in 1887 at Washington city, D. C., and

"*Whereas*, The said committee, by the letter and spirit of this resolution, was fully empowered to act, not only as a committee of invitation, but as an executive committee as well, and

"*Whereas*, The said committee, in pursuance of the objects of the above-mentioned resolution, and duly exercising the nnlimited authority delegated to it, enlarged its membership and otherwise provided for the successful holding of an International Medical Congress at Washington city, in 1887, all of which arrangements were considered by us as judieious, and, contrary to what has been charged by some, wholly disinterested as to personal or local aggrandizement, and

"*Whereas*, The American Medical Association, at its last meeting at New Orleans, did, in our judgment, unwisely and nntimely, virtually rescind its former action, which reactionary movement has deranged, if not indefinitely suspended, the work of the original committee which was satisfactorily progressing, and created an indifference to the Congress among recognized leaders of medical thought and interest throughout the country, and

"*Whereas*, There are those who persist in urging the so-called justice of their claims for the organization of the International Medical Congress on a territorial basis, which unfortunate idea has been unwisely further extended by some members of the profession in Texas in a manner calculated to arouse a sectional prejudice, which has little if any existence in our State; therefore be it

"*Resolved*, That the Dallas County Medical Society deplores what must be considered the present interregnum in the affairs of the contemplated International Medical Congress, brought about, as we believe, by an ill-considered and hasty action at the New Orleans meeting before mentioned; that this society was fully satisfied with the work of the original committee, which was composed of able, eminent, and conscientious members of the profession; that this society repudiates any attempt to inject a sectional feeling into a purely professional matter which has reference to scientific investigations only, and that said attempt, if offered in behalf of the medical profession of Texas, is, in the opinion of this society, both unauthorized and gratuitous; and that, looking beyond a narrow-minded policy of personal aggrandizement and sectional interest, we heartily commend the recent action of Philadelphia and New York brethren, as well as those elsewhere, who have retired from the Congress until a more dignified and unselfish view of the arrangements can be had; and we pledge them our hearty support and good-will in their efforts to advance the interest of the American medical profession in future meetings of International Medical Congresses, where the truly representative medical abilities of our country shall be enlisted uncontrolled by geographical lines or personal preferences."

In its editorial columns, the same journal says:

"Rapid disintegration still characterizes the new organization of the Congress. This week we are called upon to chronicle more resignations, and the list includes one vice-president of the Congress, three vice-presidents of sections, and several members of councils. The very large number of appointees who have declined to accept office under the New Orleans committee are all old-code men, both in principle and practice, and for the most part they are members of the American Medical Association. They recognize the falsity of the issues which were raised at New Orleans, and they have promptly placed their emphatic seal of condemnation npon the most disgraceful piece of intrigue which has yet marred the history of that body, and which is in imminent danger of placing an ineffaceable stigma upon the good name of the whole American medical profession.

"Although the hollowness of the code cry has been fully exposed, we still find it being freely used by the new committee, and we learn that a circular, to which signatures are invited, has been extensively circulated through this State, expressing approval of the exclusion of the new-code men from membership in the Congress and applauding the work of the committee at Chicago, and it is headed 'The Action of the American Medical Association indorsed.' The first response it appears to have elicited was the resolutions condemnatory of the action at New Orleans, which were passed by the Alleghany County Medical Society and published last week, and this week we hear the echo from Texas.

"The profession recognizes that on account of recent events there is imminent danger of its not being able to meet the obligations which it incurred by the invitation extended in its name at Copenhagen, and its members naturally look around to see what means can be found to avert the impending disaster which threatens to defile its good name.

"The clearest and cleanest way out of the false position into which the profession has been entrapped by the plotters at New Orleans is for all appointees to discredit them completely by declining to accept office at their hands, and thus their organization must, of necessity, collapse. Already this has been largely done, and upward of one hundred and twenty of the most eminent of their appointees have declined to be tools in their hands, and the sooner the remainder follow suit the sooner will the way be opened to the profession to redeem its plighted honor."

The "American Practitioner," of Louisville, says:

"At its meeting in 1884, the American Medical Association selected eight of its members to visit Copenhagen and invite the International Medical Congress, then in session in that city, to hold its next meeting, in 1887, in the United States. The invitation was given by the association in the name of the profession of America. It was accepted, and the committee which conveyed it was at once adopted by the Congress as its own, and invested with the necessary powers of organization and all its *et ceteras*. The committee, while away, acquainted itself with the accustomed mode of organizing and the methods of work of the Congress. It was informed by the founders and chief promoters of the Congress that the work of this body was confined to science, pure and simple; that every other business was vigorously excluded; that its membership was catholic in the broadest sense of that term; that it knew neither geographical lines nor sectional lines, but embraced the workers of every clime and nationality; and, finally, that the only ethical test required of applicants seeking admission was that they should belong to the universal brotherhood of legitimate science. The committee returned home and entered without delay upon the discharge of the duties with which it had been intrusted. These duties involved much labor and great responsibilities. They were completed in season to present the result in detail at the meeting of the association in New Orleans in May. The plan of organization advised by the committee was that under which all previous sessions of the Congress had been held. In a word, the committee simply acted upon information derived while abroad. This information it embodied in its report. The report itself was modeled on that of every preceding Congress.

"When the secretary of the committee read this report at New Orleans, it met with the most extraordinary reception. It was not even accorded the common courtesy of being received. Instead, it was assailed on the floor of the association in language too coarse to be repeated, and the committee itself was openly charged with narrow-mindedness, partiality, selfishness, bargain, intrigue, and corruption.

"The committee, as originally composed, consisted of Austin Flint, John Billings, Minis Hays, H. F. Campbell, L. A. Sayre, George J. Engelmann, Christopher Johnston, and John M. Browne, of the navy.

"Acting under the resolutions which called it into existence, it had added thirty-four other members, representing names in every respect worthy of being associated with the foregoing. Of this committee, consisting now of forty-three members, but five were present when the handful of agitators bent on revolution rose in the association. The

names of none of these men had appeared in the organization of the Congress, as reported by the committee.

"Many persons profess to have seen in this omission the mainspring of their action. They spoke much and often and well. They appealed to sectional prejudice and were applauded. They indulged in endless personal animadversion. The air was made thick with charges against the committee which their authors could not have believed to be true, but which, serving their purpose for the hour, they used with no little effect. The most offensive of these was reiterated with great vehemence by one of the speakers. Not many days after it was proved to be groundless, and its author branded in the public prints as a deliberate falsifier.

"During the time just described the wildest confusion prevailed on the floor of the association. Cries of 'Order' went up from all parts of the house. Scores of men rose simultaneously to their feet in attempts to catch the eye of the speaker, or to clamor for the preservation of order. The gavel of the presiding officer fairly rattled, but in vain. There was no order. An eye-witness likened the hall of the association at this moment to pandemonium.

"It is reported that one of the more violent of the revolutionists expressed a desire to see certain officers of the Congress strung up by the neck, and declared himself willing to adjust the fatal noose.

"The secretary-general of the Congress finally succeeded in getting the floor. He made a plain and manly statement of the work of the committee, counseled conciliation, and gave a flat denial to every charge reflecting upon the honor, fair-mindedness, and integrity of the committee. But his effort to stem the current was quite unavailing. The sober-minded members present sat bewildered, and the association was hurried into the deplorable blunder of repudiating the report of the committee and practically impugning the motives of the committeemen.

"In the face of its own resolution passed the year before, and under the sanction of which the work of organization had been carried on, the association declared void every addition to its members made by the committee, and took the business into its own hands. It at once appointed a member from each State and Territory, and a representative each from the army and navy—in all, thirty-eight. It then clothed this new committee with the power to undo, if it thought fit, the entire work of the committee of 1884. It gave it no instructions.

"The committee organized at once by electing a temporary chairman and secretary. It held its first meeting for business at Chicago in June. There were present twenty-five of its own members and three members of the original committee. After electing the temporary officers to the same positions in permanency, they proceeded to eject the new-coders from office and fill their places with men loyal to the old code.

"They then lessened the number of sections, as created by the original committee, by merging here and there two sections into one. They subsequently cut out many names from the North and East which they replaced by names from the West and South. They added largely to the list from the latter portions of the country, and procured a representation from a much more extensive territory than had been embraced by their predecessors in the work.

"They withdrew the right of presidents of sections to have a voice in the selection of their co-workers and associates, whereby these officers were dwarfed into mere creatures of the committee. They finally denied representation in the Congress to such physicians as were not members of the National Association, or of societies in affiliation with it. The committee then adjourned. So much by way of history. The committee made no report of its work; but its operations soon came to be known.

"The behavior of the association but sixty days before was yet fresh in the public mind. There was a widespread feeling of misgiving and regret, coupled with the hope that the Chicago committee would in some way atone for the wrong and injustice done the profession at large and the original committee at New Orleans. But its action instantly destroyed such hope and confirmed the gloomiest forebodings. The committee chose as its officers men who, whatever may be their talents, had led the movement at New Orleans, and secured themselves in office. Many physicians who had accepted position in the Congress from the original committee, despairing of the success of the undertaking in its new hands, determined to withdraw from the organization. Others, saying openly they would not serve under such officers, also withdrew.

"The meetings of the profession in Philadelphia, Boston, Baltimore, Washington, and Cincinnati, not to mention individual instances in other places, bear witness to the extent and earnestness of this feeling. Every day has brought fresh accessions to the list of those who decline to follow such leaders. And, as the facts of this unfortunate business become more generally known, it is safe to say that the list of those who distrust the leaders of the revolution inaugurated at New Orleans will grow apace.

"Much was said at New Orleans and elsewhere about the code question in connection with the Congress. Such gentlemen as have seen fit, for reasons, to withdraw from the Congress as at present organized, have been accused of being unfriendly to the code and supporters of the new code. Philadelphia was the birthplace of the code. There it was ingrafted on the constitution of the American Medical Association, and first offered as the creed of the profession in the United States; and there, if anywhere, is its spirit a living spirit, and does its letter carry the force of law. And yet Philadelphia physicians were the first to take up arms against the New Orleans movement; but the question of code was not in their minds. They well knew how adroitly and with what effect it had been used at the National Association, but, when they met to record their objections to the Congress passing into the hands of its present leaders, the code was never once mentioned. It was not thought of. The motives which influenced them and the causes which led them to decline to accept office in the Congress under its new organization were of another and very different kind. They raised no objection to the action of the committee on the code, though some of the more conservative of them may have doubted the wisdom of a step which turned upon a point that the Congress had never considered, and, from the very nature of its organization and the spirit by which it was guided, could but believe was beneath its dignity to consider.

"The Philadelphians were fully alive to the fact that, notwithstanding the war of the factions in New York, the code men continued to associate with the new coders in school, hospital, and society, and even meet them in consultation.

"When Dr. Leidy and Dr. Agnew, Dr. Da Costa and Dr. Stillé, Dr. Horatio Wood and Dr. Gross and Dr. Parvin and their coadjutors met, their purpose was to withdraw from the Congress for the simple reason of distrust in its new management. They felt aggrieved at the behavior of the association at New Orleans. They were dissatisfied with the action of the committee at Chicago, and they went to record to this effect.

"Whether the gentlemen who in other cities have come to book in similar resolutions were influenced by similar reasons is not germane here. Philadelphia led off in the movement. That this same feeling of distrust—not to use a stronger word—reaches to very many other places, no observant man will deny. That it exists to such degree, that it exists at all, affords cause for the liveliest apprehension. That it will acquire such proportions as may lead the National Association to call a halt and undo some of the work it did in such unseemly haste at New Orleans, remains to be seen.

"The conjecture is certainly grave enough to make such action reasonable. And if wisdom united to courage and the charities direct and control the association, it may still recover from the stab inflicted with its own hand at New Orleans, and bring the sessions of the International Congress in 1887 to a successful close. Otherwise the fate of the association, no less than that of the Congress when it meets on American soil, is easily read. The end of one will be disintegration and decay. That of the other will be mortifying failure. These are strong words, but sober withal.

"A medical man of Philadelphia, of enviable name, was asked a short time since by the secretary of the new committee if he could suggest a way by which the differences between the profession and the association could be adjusted. He answered, 'By your resigning.' This may, or may not, afford a key to the situation. But it clearly signifies that certain things done both at New Orleans by the association and at Chicago by the new committee must needs be undone before

surcease can be had of the present discord. If this be not effected, those who have thrown up commissions derived from the new leaders will take neither part nor lot in the matter. And while it goes without the saying that this action will in no wise affect the coming of the Congress at its appointed time, it will surely rob the meeting of all international character, which, in the opinion of its founders and its friends, has been the chief and most valuable feature of the organization.

"One or two thoughts, growing out of events which have occurred since the association meeting in New Orleans, here suggest themselves. When it is considered that almost every man who has declined to serve under the present *régime* of the Congress is a member of the American Medical Association, does it not mean that there is a strong feeling of dissatisfaction with the action of the association? When this feeling is made manifest from Massachusetts to Maryland, from the District of Columbia to Missouri, from New York to Ohio, and from Pennsylvania to Kentucky, does it not mean that the feeling is a somewhat general one? Nor should it be lost sight of that there are many sections of country which have not yet expressed themselves on the subject.

"The question has been under discussion for now a full month. Both sides have had a hearing. How stands the medical press on the subject? Let the reader turn to his journals and see. Can any of these things be denied? Is the man not purblind who fails to see that the National Association has, by its conduct, imperiled its influence and usefulness, if not its very existence? There is a profession outside the association whose voice it would be well for the present managers of that body to give ear to. The invitation to the Congress was given in the name of the profession of the United States. Perhaps the association had no authority to do this, but it was done nevertheless. The membership of the association represents but three thousand of the forty thousand men who win their bread by the practice of medicine in America. The Congress, in whatever kingdom it has hitherto held its sessions, has thrown wide its doors to all respectable members of the profession throughout the world. Neither ethics nor the matter of membership in this or that society ever came before the Congress. Its plane of work was broader and better than that. It has hitherto represented the beneficent spirit of science and that only. It has remained to the National Association of the United States to set up a new standard for admission. Fortunately, it is not too late to remedy that blunder, and such part of it at least as affects the profession at large will be changed when the new committee meets in New York in September. This will add both to the membership and dignity of the Congress.

"What will be the outcome of this deplorable muddle it is altogether impossible now to say. The committee, aided by older and wiser heads than those who have hitherto directed its movements, may hark back and find a path which will lead the association out of its present dilemma, and up to the point of organizing a truly International Congress worthy alike of its noble aims and of the great guild which bids it come to our land. If the committee fails, especially if it fails through unworthy ambition, love of patronage, or, worse than all, through greed of office, it will realize before this business is finished that wreckers are sometimes wrecked, and revolutions are often fatal to their leaders."

The "Kansas City Medical Index" says:

"It seems too bad that sectional jealousies in the United States are so great that they may be the means of wrecking the next International Medical Congress appointed to meet at Washington in 1887.

. . . . . .

"We are exceedingly sorry the affair has assumed this shape. It appears to be the opinion of many that the American Medical Association at New Orleans acted rashly and hastily in interfering in the matter, and whether they had the authority to act at all is questioned.

"There will be two more meetings of the association before the International Congress meets, hence we hope there will be time to heal old sores, and everything be made harmonious."

In a pamphlet entitled "Shadows in the Ethics of the International Medical Congress," Dr. Levi C. Lane, of San Francisco, Professor of Surgery in the Cooper Medical College, says:

"For the information of readers who have not followed the International Medical Congress through its phases of change since it was decided to hold the next meeting in this country, it may be stated that the original committee of seven men, to whom the American Medical Association in 1884 gave the matter in charge, being invested, in accordance with the act creating the committee, with full powers to perfect such arrangements as would secure a successful meeting, proceeded to outline the work that was to be done, by the creation of nineteen sections, representing in detail every department in the science of medicine.

"This division of the work, copied mainly from the method pursued at the preceding sessions of the International Medical Congress, was assigned to a like number of committees, composed of medical men selected from different sections of the United States.

"The American Medical Association, at its recent session in New Orleans, declined to accept the work done by the committee appointed the previous year, and created a new one, with instructions to revise and change the work of the former committee in whatever way it might see fit. No impartial mind will admit that there was need of revision and change of the work done by the first committee; and it is greatly to the credit of nearly one third of the delegates at New Orleans that they strenuously opposed it. What a chaplet is this discord to place on the grave of Dr. Thomas, who, in the discharge of his duties as a co-laborer with the old committee, lost his life! What a recompense to Drs. Flint and Billings, through whose personal efforts at the last meeting the Congress was induced to hold its first session in the New World! Their scourging finds an analogue in the fate of Columbus, who was borne in chains over the ocean across which he was the first to lead the Old World. How edifying this spectacle to the eyes of the Pasteurs, Charcots, Virchows, Volkmanns, Esmarchs, Listers, and Pagets, who are expected to honor with their presence the coming Congress!

. . . . . .

"I am not now, nor have I ever been, connected with the new-code movement, either here or elsewhere; in fact, the subject has never been a matter of division on this coast. I am a member of the American Medical Association, and, as a duly accredited delegate, I represented that body not long since in the British Medical Association, and my mission was not dishonored by ostentatious show there or elsewhere, during a sojourn of over two years, during which I met the leading men connected with the medical institutions of Great Britain, Sweden, Russia, France, and Germany. I am a member of, and very recently president of, the State Medical Society of California, from which Dr. Cole was sent as delegate to New Orleans.

. . . . . .

"The honors conferred on me by the original Committee of Arrangements were given unasked for. I had already sketched out some work as a contribution on a topic of surgery, in which I have had much experience; besides, I was in negotiation with a man of wealth for the establishment of an international medical prize for researches upon typhoid fever. These facts are here mentioned to show that I had not entered on this labor with an idle hand."

The "Lancet" for August 1st says:

"We regret to have to inform our readers that the ill feeling which has been excited in the United States by the action of the committees appointed to carry out the preliminary arrangements are such as to imperil not only the success of the Congress in 1887, but the very existence of the Congress itself. We have already mentioned the main facts in the dispute. At the meeting of the American Medical Association held in Washington in 1884 a committee of seven was appointed to act as a deputation to the Congress in Copenhagen to invite the Congress to the United States for its meeting in 1887. The invitation was accepted, and the committee forthwith proceeded to carry out various preliminary arrangements, and, among other matters, to make nominations for the officers of the different sections in the Congress. At the meeting of the American Medical Association in New Orleans in May of this year, a resolution was passed repudiating this latter action of the committee as being *ultra vires*, and another and larger committee was appointed to make all the preliminary arrangements for the Congress. This committee was nominated largely on a geographical basis, each State sending a representative. Very naturally this action of the association gave great annoyance to the members of the earlier committee and to their associates in the earlier steps of the proceedings. The larger committee recently met at Chicago, and issued a long list

of officers of the various sections in the Congress and of the members of committee. Many of the names on the earlier list are not to be found on the latter, and it is stated that the new list contains the names of some men introduced for geographical reasons rather than on account of their high scientific attainments—that an attempt has been made to have the officers representing as much as possible all parts of the Union. Into the merits of this question we can not enter. And now we learn that many of the leading practitioners in New York, Washington, Boston, Philadelphia, and Baltimore are so offended at the action of the American Medical Association and its new committee that they have publicly severed themselves from the Congress, and allege that they will have nothing to do with the meeting in 1887 if the arrangements for it are to remain in the hands of the present committee. We can not discuss the merits of this far from edifying quarrel, but we are too greatly interested in the International Medical Congress not to raise our voice in protest against a state of matters which is both a professional scandal and a serious peril to the continued existence of the Congress. Hitherto it has been considered binding upon all participating in the Congress that medical politics shall be entirely excluded from all its proceedings. But, apart from that, we must impress upon our American friends the simple consideration that, unless the whole profession in the United States combine cordially in the work of the Congress, the meeting in Washington is foredoomed to failure. Party spirit is so alien to the whole spirit of the International Congress that a large proportion of those who have previously joined in the meetings would certainly, and with justice, refuse to visit the United States to be the guests of a faction. But we have too high an opinion of our Transatlantic friends to believe that this unseemly quarrel, which is disgracing them throughout Europe, will be allowed to continue. We trust that moderating influences will be brought to bear upon both parties, and that, forgetting the past and their own personal predilections, they will cordially unite to promote the success of the meeting in 1887. If, however, the breach now formed is allowed to widen and deepen, it will be the duty of the officers of the Congress in Copenhagen to seek at once an invitation from some country in which the medical profession will not find it impossible to combine for international purposes."

The Health of Michigan.—We are indebted to the secretary of the State Board of Health, Dr. Henry B. Baker, for a summary of returns for the month of July. It appears that diphtheria was reported from sixty places, scarlet fever from thirty-four, and measles from fifteen.

Errata.—In Dr. Craig's article, published in our last issue, the following errors should be corrected: Page 155, in the formula, for "℥ iv" read ℥ vj; page 156, first column, twenty-third line, for "September 30th" read *September 3d.*

Phrenology and Traumatism.—"You have large imagination; you ought to write poetry," said a phrenologist to a man whose head he was examining. "I do write poetry," replied the individual, "and the bump of which you are now feeling was caused by a blow from an editor to whom I offered a poem. Please don't bear on so hard."

THERAPEUTICAL NOTES.

Odorless Iodoform.—Oppler ("Ctrlbl. f. Chir.") states that he has accidentally found that coffee completely masks the odor of iodoform. Roasted coffee should be very finely powdered, and mixed with the iodoform in the proportion of thirty, forty, or fifty per cent. The following formulæ are given:

Iodoform	2 parts;
Coffee	1 part.

Mix, with the aid of a few drops of Hoffmann's anodyne. [It is stated that the addition of the latter is not essential.]

Iodoform	3 parts;
Paraffin ointment	30 "
Coffee	1 part.

Mix; make an ointment.

The antiseptic power of coffee is mentioned as in itself an advantage.

Quillaia as a Substitute for Senega.—Kobert ("Ctrlbl. f. klin. Med.") has found senega open to certain objections as an expectorant, although its efficiency is undeniable. Its taste is disagreeable and it is apt to provoke either vomiting or diarrhœa. Its action, he states, depends on two glucosides, both of which are found in various proportions in different commercial specimens of the drug. Moreover, it is dear. The author has found that quillaia, which is much cheaper, contains about five times as much of the same glucosides, and in more constant proportion, while it is much more agreeable to the taste, and does not disturb the digestion. Clinical experience has shown him that its expectorant powers are unquestionable. He uses a decoction of 5 parts of quillaia to 200 parts of water, of which the dose is a teaspoonful for children and a tablespoonful for adults. Intestinal and gastric ulceration is a contra-indication to its use, as undue absorption by the ulcerated surfaces may lead to poisoning.

The Use of Cocaine during Labor.—Dolèris ("Compt. rend. hebdom. des séances de la soc. de biol."; "Ctrlbl. f. klin. Med.") has used cocaine in six cases of labor, either in solution or in the form of a four-per-cent. ointment, with the view of mitigating the pain of the dilatation period or that of the expulsive period. In two cases the measure failed, probably because the cocaine was decomposed by the remnants of a corrosive-sublimate injection that had previously been thrown into the vagina.

The Use of Iodine in Diphtheria.—Adamson ("Practitioner") adds his testimony to the efficiency of the iodine treatment. He lost only two patients out of fifty-five treated with the tincture alone, although some of the cases were very grave. For adults he gives from five to seven minims every hour, and for children between six and twelve years of age from two to three minims every two hours. Special mention is made of syrup of quinee for disguising the taste of the drug.

Hopeine.—This alkaloid, which appears to be different from the lupuline of Griessmayer, is described by W. T. Smith, of London ("Dtsch. Med.-Ztg."), who refers to previous investigations by Williamson and Springmühl, who gave it the name of hopeine. It is said to be most abundant in the American wild hop. It occurs as a white crystalline powder, or in the form of needles a third of an inch long. It is very sparingly soluble in water, but dissolves freely in alcohol, the solution having the most intense bitter taste and a pronounced smell of hops. Chemically, it bears a close resemblance to morphine. In its physiological action it is a pure narcotic, even fatal doses producing no irritant effect; but it contracts the pupil, raises the temperature, and increases the frequency of the pulse at first, but afterward diminishes it. The deep sleep which it induces is apt to be preceded and followed by peculiar hazy hallucinations. The author has used it as a hypnotic, in doses ranging from one third to six tenths of a grain for adults, and in his own person he found that three quarters of a grain produced symptoms of poisoning. He finds that the dose does not have to be increased on account of the system becoming habituated to the drug. He thinks that the "toxic dose" is not much above a grain and a half for adults, and not over nine tenths of a grain for children.

The Treatment of Puerperal Eclampsia with Hot Baths.—Breus ("Arch. f. Gynäk."; "Rev. méd. franç. et étrang.") reports that he has continued his experiments in the use of hot baths as a remedy for puerperal convulsions, and has now treated seventeen patients by that method, with only one death. If there is albuminuria, that, too, is favorably affected by the baths. He first puts the patient into a bath of about 100° F., and gradually carries the temperature up to 104° or 106°. He has not found that either abortion or hæmorrhage is favored by the treatment.

The Treatment of Acute Nephritis.—Aufrecht ("Berl. klin. Woch."; "Lyon méd.") advises the greatest caution in medication, and particularly the avoidance of diuretics and diaphoretics; at the most, he uses iron to combat the anæmia only after the lapse of several weeks. At the outset the patient must keep his bed, and be allowed only a minimum of nitrogenous food. Light vegetables are to be preferred, and it is only at the end of a fortnight that milk and broth are allowed. He cites the case of a child with scarlatinal nephritis who recovered under this treatment, although there had been suppression of urine for eighty hours.

THE EARLY STAGES OF HUMAN DEVELOPMENT.

BY CHARLES SEDGWICK MINOT, M. D.,
BOSTON.

PART I.—OVA OF THE SECOND WEEK OF PREGNANCY.

THERE is no comprehensive account of what is at present known of the history of the human ovum during the first month of gestation. It is the object of the present series of articles to meet this want.

The only tolerable account of what is known of the very early stages of man's ontogeny is the very admirable review indeed given by His in the first part (pp. 147–166) of his great work on the "Anatomy of Human Embryos," a work which is a veritable masterpiece of accurate and thorough research. I take the more pleasure in speaking thus as Prof. His has recently been bitterly attacked by Haeckel in a manner equally unwarrantable and ungentlemanly. It is much to be regretted that the critic should have forgotten his own repeated falsifications, instead of recollecting that Prof. His was a model whose truthfulness his critic would do well to imitate. It will be found that, although Prof. Haeckel has written a large book upon anthropogeny, yet he has contributed very little of the slightest value to the science of human embryology, while Prof. His is one of those who have done most. It is therefore most unbecoming for the former to denounce the latter with such virulence as he has displayed. Haeckel's personal dislike is not likely to affect the recognition of the sound worth of Prof. His's researches. As I shall have occasion to frequently cite the latter, it seemed desirable, in view of the criticism alluded to, to express my estimation of His's work.

The two next best general accounts are: one given by Kölliker, in his smaller Embryology ("Grundriss der Entwickelungsgeschichte," 1884); the other by Allen Thomson, in the ninth edition of Quain's "Anatomy." These authors give, I think, only inadequate summaries of our present knowledge, which is much more extensive than appears in their writings. As regards Kölliker, it should be remembered that his book is chiefly occupied with a presentation of his own observations and bears largely the character of a series of original investigations, and gives, therefore, less attention to summarizing the writings of others than might be considered desirable in an avowed text-book. The embryology in Quain, on the other hand, is professedly a summary, so that it is specially to be regretted that the distinguished author did not prepare an exhaustive revision of the literature of the embryology of the first month. The other "embryologies" appended to various "anatomies" and "physiologies" are, for the most part, second- or third-hand compilations, none of which, so far as I know, call for further notice.

Having myself undertaken to prepare a "Treatise on Human Embryology," to be published, before very long, by Messrs. Appleton & Co., it became necessary to go over the literature of the subject afresh. This study leads to results in many respects widely different from the statements which have found general currency, so that, pending the appearance of the treatise above mentioned, it has been thought desirable to publish a review of all that is at present known as to the course of development of man during the first month, adding at the same time a sufficient number of illustrations to fully elucidate the meaning of the text. This review will form a short series of articles in the pages of this Journal.

We may begin by stating that the known human ova may be divided into two categories—(1) those before, and (2) those after the appearance of the embryo. The number of the former is very small, only seven observations of any value being known to me. No ova are known which show the manner in which the embryo arises from the blastoderm, and no satisfactory description exists of any embryo younger than His's embryo L1, in which the neural tube was already formed and the brain marked out, the auditory vesicle present, etc. In fact, we possess an extremely insufficient knowledge of ova under three weeks, and it is a matter of rare interest and importance to secure and properly investigate more specimens of this period. A certain number of these come into the hands of practicing physicians; I therefore earnestly exhort the members of the profession to bear the needs of science in mind and to preserve material which none but them can secure. It may assist those who are willing to thus aid science to have some guide for finding and keeping the desired specimens; therefore a few brief directions are given below. I need hardly add that I am very desirous of obtaining young ova and embryos for purposes of research, and shall feel under deep obligation to every one who contributes material for my studies in this field. Of course I shall be happy to meet any expenses which may be incurred in sending specimens.*

1. HOW TO OBTAIN AND PRESERVE YOUNG HUMAN OVA AND EMBRYOS.

It is probable that pregnancy usually begins with the first menstruation omitted. If a woman, in whom pregnancy may be expected, and who, being otherwise in good health, has been menstruating regularly, skips a period, it is an indication that she has become pregnant. It is by no means rare that at some time after the omitted period a discharge of blood occurs, and such discharges are frequently accompanied by abortions. If, therefore, a patient, suspected of pregnancy and having uterine hæmorrhage within two months of an omitted period, be carefully watched, there is a probability of finding an ovum or an embryo among the discharges from the uterus, and all such discharges of blood or decidual tissue should be carefully examined.

If the disturbance occurs within fourteen days of the omitted period, search should be made for a small, flesh-colored vesicle, either with short villi or with a partly or wholly smooth surface. The vesicle will be from one ninth

* Dr. Minot's address is: Harvard Medical School, Boston, Mass.—EDITOR.

to one fourth of an inch in diameter (3 to 6 mm.). It should be treated with the greatest care, and on no account be placed in water or opened. If the disturbance occurs after a longer interval, a larger vesicle must be looked for, with the villi much longer and more ramified. As long as the vesicle measures less than three fifths of an inch (15 mm.), it should be preserved *unopened*. If the ovum is larger than this, it should be carefully examined to ascertain where the embryo is attached to the walls (chorion) of the vesicle, and then the opposite side of the vesicle slit open with fine scissors, to allow the preserving fluids to penetrate.

To Preserve Ova and Embryos.—Above all, NEVER place them in water or in strong alcohol; when possible, put a little cotton-wool in the preserving fluid for the specimen to lie upon. If it is necessary to carry it a short time before the preserving agents can be obtained, wrap up the specimen in a damp, soft cloth, taking care to avoid all pressure upon it.

The best method of preservation is, on the whole, by Kleinenberg's picro-sulphuric acid, which is made by dissolving 0·1 gramme of picric acid in 100 c.c. of water, and adding 0·6 cubic centimetre of concentrated sulphuric acid. Leave the specimen in this solution for one or two hours, according to its size, wash it for a few minutes in alcohol of 30 per cent., place it for an hour in an alcohol of 50 per cent., and then transfer it to alcohol of 70 per cent., in which it may be kept permanently; but the alcohol must be renewed until it is no longer discolored by the picric acid.

A good method, and much simpler, is to put the embryo or ovum for five minutes (but on no account longer) in a mixture of one part of concentrated nitric acid with ten parts of water. Then transfer to 70-per-cent. alcohol.

The third and simplest method is to place the embryo directly in 60-per-cent. alcohol, in which it may be kept, or, better, placed after two days in alcohol of 70 per cent.

Apothecaries can furnish alcohols of the desired strengths. All these methods require care; but the value of the specimens fully repays the trouble.

In sending or transporting the specimens, the jar or bottle should be very lightly stuffed with fine cotton-wool, and it must be remembered that a very slight pressure of the wool will distort the specimen. All that is needed is to prevent the specimen from shaking about.

2. KNOWN OVA OF THE SECOND WEEK.

Reichert's ovum (1) is to be considered the youngest normal human ovum hitherto described. It was thought by Reichert to be twelve to thirteen days old, and probably correctly so, as it was obtained at a post-mortem examination of a young German girl under circumstances which render the estimate of the age quite trustworthy. The ovum itself was very imperfectly examined by Reichert, whose very lengthy memoir deals largely with cognate subjects and contains much speculative matter. The actual description of the ovum is brief (pp. 25–28); but, as far as he went, Reichert worked with exemplary accuracy, and this renders his research valuable.

The ovum in question was a flattened sphere, with a short diameter of 3·3 mm. and an equatorial diameter of 5·5 mm.; smooth around both poles, and with a marginal or equatorial zone of villi separating the two smooth areas.

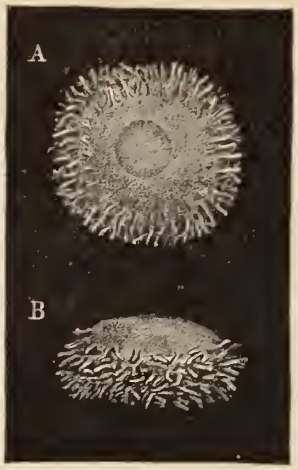

FIG. 1.—REICHERT'S OVUM. Two views engraved from the original plate.

The smaller and flatter of these two areas faced the uterine wall and bore on its inner surface (*i. e.*, within the ovum) a small accumulation of rounded cells. The opposite area was more convex. The villi were short (0·2 mm.), thick cylinders, with rounded ends and no branches. The walls of the vesicle consisted only of epithelium, which also formed the simple hollow villi. The contents of the vesicle were: 1. The inner cell-mass, lying, as before mentioned, at one pole. 2. A network of threads, apparently the result of coagulation of the contained fluid, for no nuclei were found in it. Kollmann (7, 294) thinks that Reichert's ovum must have had really two layers forming the vesicular walls —an inner one of mesoderm (young connective tissue), and an outer one of true epithelium; further, that the true epithelium had been lost, and that only the connective tissue remained, which Reichert mistook for epithelium. This supposition is, I think, not probable. Reichert's ovum is, presumably, younger than any other hitherto described, and may well have been in the stage before mesoderm had grown over the chorion. The villi are described as hollow by Reichert—a statement not compatible with the supposition that he mistook a solid core of mesoderm for the hollow shell of ectoderm. Indeed, it is probable that the young villi contain no mesoderm at first.

Breus's ovum (2) must be considered further advanced than Reichert's, although the author fixes its age as presumably ten days. The total diameter of the ovum, including the villi, was only 5 mm., and, as the villi were about 1 mm. long, the diameter of the chorionic vesicle must have been about 3 mm. The villi, some branched, but mostly without branches, were thick-set, but left one spot bald, agreeing in this with Jones's ovum (see below). The chorion was smooth on its inner surface, and consisted of (1) an outer epithelial layer, and (2) an inner connective-tissue layer, which sent out extensions partly filling the villi. The ovum contained a thready mass which Breus thinks was probably a product of coagulation, and an inner cell-mass about 1 mm. long and 0·5 mm. wide. The presence of villi

and the existence of the mesodermic layer of the chorion, contrasted with the absence of any embryonic structure, led Breus to consider his ovum abnormal. But it is rather the contrary conclusion we must draw, since all our knowledge points to the deduction that, as compared with the embryo, the development of the chorion is very precocious in mammalia. I deem it therefore probable that Breus's ovum was normal.

Wharton Jones (3) long ago described briefly a human ovum the chorion of which measures in his figure (said to be natural size) 6 by 4 mm.

The following is all that can be gathered from Jones's description: The ovum was already covered by the decidua, and bore shaggy villi on the side *toward* the uterus, while the other side was bald. "The whole cavity of the chorion was filled with a fine gelatinous cellular * tissue, imbedded in which, toward one extremity of the ovum, was a small round body; it was evidently the vesicular blastoderma. On being taken out and examined under the microscope, it presented the same friable, globular structure found in the vesicular blastoderma of the rabbit in the preceding observation. There was no vitellary membrane to be seen." To judge from the minute figure given, the villi were already branched; in Reichert's ovum they were still simple.

Ahlfeld's ovum (4) represents, perhaps, the same age as Jones's, but he does not give its diameter, which appears, from incidental references, to have been about 5 mm. The author's description is not exhaustive by any means, but he mentions two points of great interest—*first*, the presence of a layer of connective tissue (mesoderm) underneath the chorionic epithelium, and extending into, but only partially filling, the villi of the chorion; *second*, the character of the villi, which are slightly branched and are constricted at the base; only their tips touched the surface of the decidua (reflexa and serotina). He also states that the epithelium of the villi precedes in its growth the connective tissue. This ovum was supposed to be fourteen to sixteen days old (?). Owing to an accident, no observations of its internal contents were made.

Beigel's ovum (5), of which he maintains that it is the third smallest known, is, if we may judge from his plate, certainly abnormal to an extreme degree. I hold it to be a malformed ovum of the fifth or sixth week. The ovum described by Beigel and Löwe (6) is of an even more questionable character. Moreover, their account is considered by Breus and Ahlfeld to be very inaccurate. It is noteworthy that Beigel and Löwe have also noticed the early presence of the mesoderm under the chorionic epithelium. Löwe (6 A) defends himself against Ahlfeld's attack, and insists, with justice, upon the presence of connective tissue on the inside of the chorion in ova of the second and third week.

Kollmann's memoir (7) is by far the most valuable which has hitherto appeared upon the structure of very young human ova. He describes two ova, *a* and *b*, both preserved in the anatomical collection at Basle. Ovum *a* had been placed in glycerin and water, which preserved the form of the specimen but ruined it histologically; nothing was made out as to the contents of the chorionic vesicle. The vesicle itself measured 5·5 by 4·5 mm., and, therefore, was slightly flattened. This measure does not include the villi, which were from 1 to 1·2 mm. long, and repeatedly branched. Ovum *b*, 5·5 mm. in diameter, was well preserved in alcohol; the villi were somewhat branched; the contents of the ovum were lost. On the other hand, the uterus belonging to this ovum was also preserved, and forms the basis of a very valuable description of the uterus in early pregnancy, to which I hope to recur on another occasion.

Kollmann's two ova are both much more advanced than those of Reichert, Breus, and Jones, as is shown by their greater size and the branching of the villi. It is a matter of profound regret that only the chorion was left, but, fortunately, Kollmann has taken good advantage of his opportunity. His paper also gives an excellent critical analysis of nearly all the previous literature.

He points out that the two primitive layers of the chorion are probably normally present at this age. The chorion of his ova, he says, consists of "einer Lage jugendlichen, embryonalen Bindegewebes, das zahlreiche Rund- und Spindelzellen enthält, und das bedeckt wird von einer einfachen Lage platter Zellen" (p. 293). He then passes the literature in review and insists strongly upon the fact that the two layers have been distinguished in nearly all the very young human ova known except Reichert's. Kollmann, therefore, as was mentioned above, questions, I think, without sufficient foundation, the accuracy of Reichert's account. Concerning the connective-tissue layer Kollmann says but little. As regards the epithelium, he points out that the nuclei occupy a basal position, so that the outer parts of the cells form a granular stratum, which some authors have considered a distinct membrane. The author supposes this granular stratum to become the cuticula described in later stages. Jassinsky (9) has given the extraordinary name of *tunica propria* to this cuticula—extraordinary because "tunica propria" is used technically to designate the connective-tissue layer upon which an epithelium rests, and never for an external cuticula. For his supposition Kollmann gives the reason that in an ovum of four weeks he found that the layer had become thinner, more resistant, and less granular—in short, had assumed something of a cuticular character.

Finally, Kollmann adds (p. 297, ff.) observations on the growth of the villi in ova of the fourth week. The outgrowth of branches is very rapid and occurs with every degree of participation of the connective tissue. There are two extremes: 1. A bud, consisting wholly of epithelium, which may stretch out into a process with a long, thin pellicle and a thickened end, the whole remaining until it has become quite large without any connective tissue. 2. A thick bud with a well-developed core of connective tissue; such a bud probably grows out as a nearly cylindrical branch. Between these two extremes every intermediate state can be found. The various forms of growing branches may lie close together. Probably this complex mode of growth persists in older villi, which would explain the multiplicity of forms in the villous branches

* This was written in 1837. "Cellular," of course, does not refer to cells in the sense of the term as used in modern histology.

Schwabe (9) has described an ovum which he considers thirteen to fifteen days old, but he is certainly mistaken, since both the data he gives as to the age and his account of the embryo show that it is more advanced, and belongs distinctly in the third week.

In connection with Kollmann's observations we must notice those of Orth (10), who has shown that at all ages, even at full term, the villi of the chorion in the placenta have epithelial buds, which are at first hollow and are afterward filled up with a vascularized ingrowth of connective tissue. *Apropos* of this observation Orth discusses Boll's theory of growth, making the point that in this case the shaping of the parts depends primarily upon the growth of the epithelium. Boll had maintained as a general principle that in the development of organs the shaping is dependent on the co-operation of the epithelial and connective tissues. Against Jassinsky (9) Orth observes that the epithelium covering the chorionic villi has only a single layer. There can be little doubt that Jassinsky was in error in stating that at certain stages the villi are covered with two epithelia, one right over the other. This mistake agrees with the false notion that the villi are covered by maternal tissue, for it might be assumed that one epithelial layer was derived from the uterus. All the best observers agree that the villi have only a single layer, the chorionic epithelium, on their surface. It is easy to verify this observation.

Summary.—From the preceding review the following conclusions may be drawn: The result of segmentation of the human ovum is the production, by the twelfth or thirteenth day, of a rounded sac of epithelium, three to four mm. in diameter; at one point there lies against the inside of the vesicle a little accumulation of rounded cells, which, from analogy with the ova of mammals, must be considered as marking the germinal area out of which the embryo is to be formed. The epithelial sac, to which the name of chorionic vesicle may also be applied, bears an equatorial zone of short villi. This stage is represented by Reichert's ovum, Fig. 1.

In the next stage the villi have spread over the germinal area and have become slightly branched; the villi next appear over the opposite pole of the ovum and rapidly increase their length and ramifications. The germinal area faces the uterine wall (Jones's ovum).

By the time villi are present over the whole vesicle there is probably always a layer of connective tissue underlying the epithelium (Breus, Ahlfeld, Löwe, etc.), but no embryonic structures have been recognized. The ova of twelve to fourteen days are already completely inclosed by the decidua (reflexa and serotina); only the tips of the villi adhere to, or are even in contact with, the decidua; this is the only connection between the maternal and fœtal tissue, for neither does the uterine mucosa grow in between the villi, nor do the villi penetrate the cavities of the uterine glands.

The epithelium of the chorion and villi is only imperfectly marked with boundaries for the single cells; its nuclei all occupy a basal position, leaving a distinct outer layer, often mistaken for a separate structure. The epithelium forms buds, which become branches of the villi. These buds may grow out to a considerable size without connective tissue (hollow villi), or the connective tissue may penetrate into them from the start (solid villi).

The human ovum, then, is remarkable for its precocious development of the chorion, both as regards the villi and the connective tissue or mesodermic layer, and for its early complete encapsulation by the decidua. All these events (according to the scanty observations yet made) precede the appearance of the embryo. It is also noteworthy that the villi are first developed around the equator, next over the germinal area pole, and, last, over the area of the opposite pole.

PROFESSIONAL ETHICS.*

By the Hon. W. H. H. RUSSELL.

Mr. President and Gentlemen: When our efficient and ever-zealous brother, Dr. Brill, notified me a few days ago that at this meeting you would expect a paper from me, the inquiry at once arose in my mind as to what *theme*

* Read before the Society of Medical Jurisprudence and State Medicine, May 14, 1885.

would best suit the *complex* mental equilibrium of the members of this association (the term complex is good, because Southworth well observes, "The parable of the wedding supper comprehends in it the whole complex of all the blessings and privileges of the Gospel"). So the complex mental equilibrium of the professions of medicine and law comprehends all there is of worth and glory in those two professions to the outer world, when practically exemplified. We looked over the subjects and titles of the previous productions, and came to the conclusion that perhaps a few thoughts upon *Professional Ethics* might interest and entertain you, and, perchance, awaken new and more vigorous interest in the objects of this and kindred associations. And, after listening to the very able and eloquent address of Parke Godwin the other evening at Association Hall, upon the problems of social science, under the anspices of the "*Institute of Social Science*" (of which he is president), I am pleased with this opportunity of offering a few comments that may at least provoke a discussion on your part and engender a spirit of strict professional pride in the great callings in which the members of this society are battling the stern realities of life.

On the 3d of March, 1883, this society was regularly incorporated under the laws of the State, under the *name* and title, "*The Society of Medical Jurisprudence and State Medicine*," with this significant declaration in its charter and by-laws: "*The object of this society shall be the investigation, study, and advancement of the science of medical jurisprudence and State medicine, and the attainment of a higher standard of medical expert testimony.*"

A most laudable purpose, with a most glaring public necessity for the complete success of its mission.

How can its objects be fully attained? is the question which should most interest its founders and members. As this world goes to-day, most men are actuated by motives of gain, either of a financial or popular nature, and the impatient *push* of business life leaves little inclination or time for calm, reflective, philosophic thought or action. And the standard nowadays by which men are gauged is the accumulation and possession of wealth and the display thereof. Money is the sovereign power before the golden throne of which men and women of genius, talent, and culture must bow, as if involuntarily drawn by her magical wand.

Success in money getting and saving is the best evidence of merit and success, say the neophytes of popular praise and ambition, and the man who clips his coupons and counts his thousands is courted and favored, while the brain worker of true merit struggles along the rugged journey, necessarily content with a bare pittance of subsistence. Parke Godwin's theories and suggestions as to the solution of the difficult problems of social science were very clever and plausible, and, if that learned and cultured gentleman can make his eloquent sayings and doctrines practiced through the medium of the organization which he inaugurated on the evening of the 7th inst. by his very able and interesting address, he is indeed one of the greatest philosophers and philanthropists of the nineteenth century.

All reforms and great remedies must be founded in the proper education of the people as a mass, and all praise and success to his noble enterprise.

Many years ago the "American Medical Association" was organized and founded in the old city of Philadelphia (patriotically known as the cradle of American independence), and, from the various "codes" of "medical ethics" down to that of most recent date, we would naturally infer that the standard of *professional ethics* in that learned profession is fully established and recognized. Section 1, Article I (under the caption), "*Of the Duties of Physicians to Each Other and to the Profession at Large, and Duties for the Support of Professional Character*," third edition, 1882, provides as follows: "*Every individual on entering the profession, as he becomes thereby entitled to all its privileges and immunities, incurs an obligation to exert his best abilities to maintain its dignity and honor, to exalt its standing, and to extend the bounds of its usefulness . . . .*" If that provision was practiced and enforced, there would be no quacks, no charlatans, and no frauds in this great science, which Æsculapius, long centuries ago, would have made the pride and glory of his age and the generations to follow.

On July 1, 1878, some of the most eminent lawyers in this country—William M. Evarts, of New York, Benjamin H. Bristow, of Kentucky, George Hoadley, of Ohio, Henry Hitchcock, of Missouri, Charlton Hunt, of Louisiana, Richard D. Hubbard, of Connecticut, Alexander R. Lawton, of Georgia, Richard C. McMurtree, of Pennsylvania, Stanley Matthews, of Ohio, E. J. Phelps, of Vermont, John K. Porter, of New York, Lyman Trumbull, of Illinois, Charles R. Train, of Massachusetts, and J. Randolph Tucker, of Virginia—issued a call to distinguished members of the Bar to meet at Saratoga in August of that year for the purpose of organizing an "*American Bar Association.*"

The meeting was held, and a constitution and by-laws were adopted, with the name and object declared, as follows:

ARTICLE I. "*This Association shall be known as 'The American Bar Association.' Its object shall be to advance the science of jurisprudence, promote the administration of justice and uniformity of legislation throughout the Union, uphold the honor of the profession of the law, and encourage cordial intercourse among the members of the American Bar.*"

Thus, in a national sense, these two professions have proclaimed, by organic provisions, the promotion of *jurisprudence* and a *higher standard* of professional honor and ethics in the United States. State and local organizations of the same character have been established in every section of the Union, and there can be no question but that, if the objects as declared were carried into effect, we would to-day behold a very different status of professional life and standing in every community. By organized unity of purpose and action, men and people may be educated to recognize the force of discipline and the worth of true merit and character.

For instance, if in the profession of the clergy there could be found the high-toned elements of courteous and genial deportment, in that all their efforts were in harmony with one great purpose, and that the unbounded happiness of the human family, irrespective of any particular

creed or sect, what a halo of glory would mantle every temple of worship that lifts its spires heavenward! If every student, scholar, and expert in medicine were to practice the profession with one common purpose, and that the true relief of suffering humanity, what a world of pleasure this might be! And if every lawyer and disciple of the great Blackstone, Story, and Kent were to exemplify the true principles of law, equity, and justice, what a magnificent system of jurisprudence we would have in this country! Government, society, and religion would then triumize and glow more beautiful than the prospective electric light which is to gleam and glitter from that noble gift of warm-hearted France which is soon to ornament our harbor as the ideal statue of "*Liberty enlightening the World.*"

Professional ethics, if developed, practiced, and encouraged in America, can do more for the future perpetuity of our republic and institutions than any other element in the social fabric.

Necessarily the toilers in the other vocations of life look up to the professions for examples of true manly character, and in the three great professions of *divinity*, *law*, and *medicine* you may find the framers of laws, customs, and usages of society. The moral maxims and the elements of true civilization are more or less formulated, crystallized, and promulgated from these three channels of intersocial and state life. The records of the National Congress of the State and municipal governments show that in the legislation of the country they have been the foremost workers in reforms and great measures (*i. e.*, the true ones of the professions), and they have always been found upon the side of good government as against the false ones of their respective callings.

During the fourteenth century, nearly five hundred years ago, the profession of the law was guarded by special acts of Parliament, which provided, among other prerequisites of admission to the Bar, that none but "*good* and *virtuous*" *men*, "*learned* and of *good fame*," should be sworn as attorneys, and that before their names could be put upon the roll they should be examined by the justices; and that, "*if any such attorney be found in any default of record or otherwise, he shall forswear the court and never after be received to make any suit in the courts.*"

If such a law was in force in this country to-day, what a weeding out there would be! In those days the employment of attorneys was *pecuniary*, *i. e.*, they were entitled to fees, while that of *barristers* was honorary. Attorneys could recover their fees *in assumpsit*, while barristers could claim nothing, at law or in equity. Attorneys were liable for neglect of ordinary care and diligence of their clients' interests.

The attorney could confer directly with his client; the barrister could not. The attorney prepared the facts and the brief, and the barrister took charge of the cause in court; and to a certain extent the same system prevails in England to-day. This system has never been introduced into this country, although Judge Story, who was the exemplar of the exalted functions of the Circuit Court of the United States for the little State of New Hampshire, did confer the degree of Sergeant-at-law upon Jerre Mason and Judge Smith, and that of Barrister-at-law upon Daniel Webster.

It must be admitted, by those familiar with the system of English jurisprudence, that to-day there is greater protection to *life*, *liberty*, and *property* in Great Britain than any other section of the civilized world, and that an English subject is protected in all quarters of the globe. I remember well, while in London in 1871, the impressions then made while in the Mansion Court of that great city. Two boys, about twelve and fourteen years of age, were called up before the magistrate for the violation of some city ordinance; the magistrate was a man of about fifty years of age, and looked the personification of a *human* judge. After the officer who had arrested the boys had given his evidence, the justice told the boys to stand up, and then asked them what they were doing when the officer had found them. The oldest boy replied that they had started for the country, and had got that far, and, not having any money, had crawled into the boxes to sleep during the night. The justice, who was able at a glance to distinguish between a bad boy and an unfortunate one, said: "Boys, go into the country and stay there; work in the fields, and stay away from the great city"; and, turning to the clerk of the court, he said: "Mr. Clerk, give those boys a shilling apiece"; and then, looking at the officer who had arrested them, he said: "And you, Mr. Officer, see them well on their way to the country before you leave them."

I wish some of our American magistrates could have seen the expressions upon those boys' faces as they left that court-room.

It was worthy of the finest touch upon canvas and the most exquisite and delicate chipping of the greatest sculptor. If our court-houses were, indeed, *temples of justice*, what a sublimity there would be in the practice and *magistracy* of the *law!* If the high-minded and good men of the learned professions of medicine and law, and I may add the ministry, would strike hands and say there shall be a higher standard of *professional* ethics in the United States, we would not read of such scenes as occurred the other morning in one of the courts of this city, where the justice from the bench, in open court, rebuked a *pseudo* medical expert by saying: "The city ought to put another such a doctor upon the pay-roll."

NUMBER OF LAWYERS, MINISTERS, AND DOCTORS IN THE UNITED STATES.

It may be of interest to know the proportions of the great professions in this country to each other and the community at large.

In 1850 there were in the United States 23,939 lawyers, 26,842 clergymen, and 40,564 doctors. In 1880 there were 64,137 lawyers, 64,698 clergymen, and 85,671 doctors—in all, 214,506. In the thirty years from 1850 to 1880 the professions more than doubled in membership. In 1850 there was one lawyer to 964 people, one clergyman to 864, and one doctor to 569. In 1880, one lawyer to 782 people, one clergyman to 775, and one doctor to 585.

Of these 214,506 professional brain workers in 1880, there were of the 64,137 lawyers 75 females, of the 64,698

clergy 165 females, and of the 85,671 doctors 2,432 were females; 64 of the 75 female lawyers were under sixty years of age and 11 over; 140 of the female clergy were from sixteen to sixty years of age and 25 over; 2,268 of the female doctors were between sixteen and sixty years of age and 164 over. Of all the three professions, 193,294 were under sixty, and 21,212 over sixty years of age. If the *pro rata* increase of population continues in the next century as in the past, there will then be a population of over 200,000,000, and over 200,000 lawyers, ministers, and doctors, in proportion as before.

Cast your horoscope of thought over the progress in this country for a hundred years to come and, if possible, calculate the effect upon the people at large if every lawyer, doctor, and minister would be true to his calling. If there was a code of ethics with the clergymen of this country which would harmonize with the great doctrines taught by the Founder of their faith, before whom it is said the wise men of the East bowed with reverence and consecrated the lowly manger as the cradle of Christian civilization, there would be no occasion for a congress of churches.

The true and noble-hearted Dr. Howard Crosby, of this city, in his excellent paper before the Congress of Churches at Hartford, on the 11th inst. (as reported in the "Herald" of the 12th), gave three substantial reasons why a code of ethics should be established among the ministry of this country; and, if his suggestions were adopted by every fair-minded worker in that exalted profession, America might become the imperial jewel in the progress of Christian civilization. All praise to his philanthropic efforts.

If in the profession of the law there was a well-established, recognized code of *legal ethics*, there would be no *shysters* and *scapegoats of unscrupulous villainy*. For, as England's great premier, Mr. Gladstone, well said, in a recent address: "Considered as a mental training, the profession of the Bar is probably of its kind the most perfect and thorough of all professions."

If, as a profession, it is followed and practiced in the true spirit of the law and of justice, every conscientious lawyer must be true to the State, the people, his clients, and his cause. He must be as the great Blackstone (the father of the common law) once poetically wrote:

"To Virtue, and her friends, a friend,
Still may my voice the weak defend.
Ne'er may my prostituted tongue
Protect the oppressor in his wrong,
Nor wrest the spirit of the laws
To satisfy the villain's cause."

And yet it is the most abused of all professions, and people are apt to think that a smart lawyer must necessarily be unscrupulous, that his conscience must be as plastic as a rubber band, to contract or expand as the case requires; and history affords some latitude for such insinuations.

It is said that when Peter the Great visited Westminster he saw many oddly appareled persons, whom, upon inquiry, he learned were lawyers, and he was so amazed that he exclaimed: "What, all these lawyers? I had but two in all my dominion, one of whom I hung, and I intend to hang the other as soon as I get home." It is not recorded that he kept his word, and, in fact, it is seldom if ever that you read or hear of a lawyer being hung, while it is not an uncommon event of late years to read of a doctor being executed. It should not be forgotten that the cradle of the resurrection was a lawyer's grave, and that a lawyer was the only man in all Jerusalem who had the moral courage to approach Pilate and demand that the body of the Saviour of mankind should be taken down from between the thief and the robber and placed in his own sepulchre. And, on another occasion, it was a lawyer who, by his undaunted courage and eloquent appeal, saved the Disciples from being set upon by a mob and slain, and thus the greatest authors of the New Testament were saved.

Shakespeare presents us with the ideal advocate in the play of the "Merchant of Venice," and Dickens, the greatest characterizer of later years, gives us his typical jurist in the personage of the "little judge" who presided in the famous case of Bardell *vs.* Pickwick, who was so exact in the rigor and spirit of the law that he would not excuse the chemist whose assistant did not know the difference between oxalic acid and Epsom salts. If some of the druggists of to-day would remember that fact there would be less danger of poison from drugs.

Nice and elegant distinctions should not be made to the detriment of the profession at large—as in the instance of Prof. Huxley, who relates of a distinguished surgeon who (being irritated by the pretensions of some physicians) was asked if he meant to bring up his boy to his own calling, replied: "*No, my son is such a fool I mean to make a physician of him.*" Or as, on another occasion, two gentlemen were discussing the old proverb, "*At forty a man must be either a fool or a physician*," when the other replied: "*True, but don't you think he may be both?*" Or that of the Irish physician who, while dining with Theodore Hook (who remarked: "I should like to place over my door an inscription, either in Latin or Greek, borrowed from one of the great authors"), at once suggested, "Give Italian the preference; nothing can equal that verse of Dante's, '*Abandon hope, all ye who enter here.*'" Sir Astley Cooper, the great surgeon, openly discredited the science of medicine "*as one founded upon conjecture and built upon murder.*" Or as the German wit said: "*Physic always does good, if not to the patient, at least to the apothecary.*" And in France the young medical graduate is spoken of as "*licensed to kill.*"

When a man dies suddenly, without having been attended by a doctor (says a humorous writer), the coroner has to be called in and an inquest held to ascertain the cause of death; but, he adds, when he dies after having been attended by a *doctor*, then *everybody knows why he died*, and an inquest is not necessary.

Or as a German paper has it in humorous dialogue shape, the child going to inform the pastor of the death of it father:

Child.—"Herr Pastor, my mother sends me to tell you that father died to-night."

Pastor.—"Did you send round for the doctor?"

Child.—"No, Herr Pastor, father died of himself."

And again as illustrated by the nurse in the hospital

in reporting to the physician in the morning: "*Six of the fever patients have died, sir.*"

"Why, I wrote prescriptions for seven," mused the doctor as he passed on into another ward.

"Yes," said the faithful nurse, "but one of them wouldn't take his."

In Russia they say the doctor seldom takes physic, and in Spain proverbial aphorisms are numerous, such as "The earth covers the mistakes of the physician," "The doctor is to be feared more than the disease," "Physic is a curse to humanity," "It is God that cures, the doctor gets the money." And one of the most common sayings in Portugal and Spain is, "*If you have a friend who is a doctor, take off your hat to him and send him to the house of your enemy.*"

Or like one of our doctors who upbraided some of the workmen the other morning for the careless manner in which they were replacing the earth over the gas and telephone pipes in the city, one of them looked up and good-naturedly said: "*Faith, Doctor, ours are not the only mistakes the earth covers.*"

These instances are recited for the purpose of showing that the doctors are subject to frequent abuse and unjust insinuations. If the prescriptions and remedies cure, their services are cheerfully rewarded; but if the patient languishes and dies, then follow too often dissatisfaction and unjust abuse. Some other doctor may say that there was not a proper diagnosis, and that from his prognosis the patient might have lived. Professional ethics forbids such deportment, and we believe that if the medical colleges and schools would establish one common medical *curriculum*, with fixed grades of graduation, and then the profession at large would enforce a uniform code of medical ethics, there would be better doctors, physicians, and experts, and less abuse. If the colleges, schools, and societies unite and work together, and the doctors, as a profession, regulate the ethics of practice, you can secure laws in every State that will protect the people from imposition and the profession from quacks and renegades.

An eminent English author, Mr. Palgrave, in his excellent work, "Rise and Progress of the English Commonwealth," says: "Man never begins by introducing any law which is entirely unreasonable, but he frequently allows a law to degenerate into folly by obstinately retaining it after it has outlived its application."

And Goethe in "Faust" thus poetically exclaims:

"Laws, like inherited disease, descend;
They slyly wind their way from age to age,
And glide, almost unseen, from place to place.
Reason to nonsense grows, a benefit to plague.
Woe unto thee, that thou a grandson art
Of inborn law, to which each man has right;
Of that unfortunately there is no question."

It can not be doubted or questioned but that there is need of great reforms in law and medicine. And, if the members of those two professions were guided and governed by well-established *codes of ethics*, they could accomplish any reforms they might wish.

And then we should have medico-legal societies that would produce experts who would be ornaments to the professions and the homes of our country, and an honor to the age. Can we have them? Yes!

The ideal lawyer, as presented by that distinguished Nestor of the New York Bar, David Dudley Field (in his recent address before the law students of Dalhousie College, at Halifax), "*is one who is master of the laws of his own country and a student of other laws as they may serve to elucidate or improve his own; a faithful adviser, a fearless defender, prompt to make use of his learning and opportunities, not only for the protection of his own clients, but for the improvement of the laws themselves, whenever he finds them the instruments of injustice.*"

And may we not look beyond the disc of his immediate orbit and say, in addition, that the ideal lawyer is he who, while faithful to the principles of his profession, does not delay justice by unfounded objections, nor increase the expense of litigation by imposing unjust costs and hindrances?

The present system of costs in this State is one of the most iniquitous ever tolerated in any civilized community; it is in many respects extortion, and almost robbery. It takes from the pockets of the unsuccessful litigant money—not to defray the necessary and legitimate expenses of the court, but to line the pockets of the counsel of the prevailing party; and the Courts have recently held that the attorney has a lien upon the costs as against all equitable offsets or counter-claims. The lawyer should not be entitled to the costs of the case; they should be light and go into the county treasury for the necessary expenses of the courts, in paying the salary of its officers, and the jury-fees. The lawyer should, like every other citizen, make his contract with his client, and stand upon that contract without the aid of the Courts and the machinery of justice to facilitate him in making the costs unjust and burdensome to the litigant and citizen.

Some of you may have noticed the other day, in one of our most enterprising papers, a statement to the effect that a citizen who brought suit on a $400 claim realized $190 on the property sold under execution, and thereby became liable for over $1,200 costs which had accrued in the case during the process of litigation. A code of legal ethics would not permit of such infractions upon the fundamental principles of justice.

The very able paper by Judge Hull upon expert testimony, read before this society, clearly illustrated the necessity of concerted action in the two professions for complete codes of professional ethics.

And the somewhat noted will case now under investigation in the Surrogate's Court reveals the fact that a pretentious lawyer, who, as reported, was a pawnbroker a few years ago, wants $3,500 for the original draft of a will, and $3,500 for attending the contestant in a police court. And the expert in the case, on Tuesday last, when asked by a distinguished substituted counsel if he had prescribed for mania, said, "*Yes; I don't remember what I prescribed, how much I prescribed, or anything about it.*" And then, being asked if he was a mad doctor, replied: "No more than a horse-chestnut is a chestnut horse."

A high standard of professional ethics in the professions

of law and medicine, enforced by such organizations as this, and the Bar and medical associations of the country, would bring about a better class of experts and a more honorable and respected status of the professions.

Lord Mansfield, one of the brightest and greatest of England's jurists, said: "*Jurisprudence is a rational science, founded upon the universal principles of moral rectitude, but modified by habit and authority.*"

What we need to-day in this country is *reform in legal jurisprudence* and *reform in medical jurisprudence*, so that when a man dies, if he is fortunate enough to possess millions, his life and his memory may not be shadowed by the unlicensed latitude of unscrupulous lawyers and doctors, who do not comprehend the domain of decency nor understand the first principles of medico-legal jurisprudence. We could then say, in fact, The true physician is he who has a proper conception and estimation of the real character of his profession; whose intellectual and moral fitness give him weight, standing, and character in the consideration and estimation of society and the public at large. He is to a certain extent the servant of the community in which he resides; he is subject to the call of the sick and suffering in the humblest and lowest walks of life, and even the bedside of the most penitent and worldly may command his presence, his skill, and aid. From the lowly, languishing couch of the weary, wanton, unfortunate waif of society to the sacred sanctum of marital purity he will be summoned at all hours of the day and night to relieve and alleviate the pains of suffering humanity.

His privileges and powers for good or for evil are great; in fact, no other profession, calling, or vocation in this life occupies such a delicate relation to the human family.

In every household, at every fireside and in every chamber, the good and true physician is a welcome visitor; his genial face, his kind and courteous treatment, and his manly deportment will always secure for him the blessings of the domestic circle. The domain of the sacred home is the empire of his glory.

The fond and affectionate mother, in that tenderest and most delicate of human reality, will intrust to him not only her own safety and welfare, but that of her offspring (the brightest jewel of ennobled womanhood); and then, in after years, when the cares of life are over and the mystical spark is about to leave the earthly tenement of frail mortality, the family physician will be called upon in the last moments to close the once beaming eyes that were the windows of the soul, and impart the information to the weeping children and friends that death is triumphant beyond his skill or power; and thus, from the cradle to the threshold of eternity, the *true physician* becomes the ministering angel of wasting mortality. He can not overestimate the responsibilities of his profession as physician and humanitarian. The American *nation* proper are greatly in need of such medical advisers. Fashionable society, in the maudlin light of popular display, is pressing out the fountain-life of true maternity and healthy progeny.

Conceptive preventives and abnormal deliveries are of too frequent use and occurrence for healthy *national growth* and perpetuity. If the family can be limited to one or two children, and perhaps none at all, elegant society is delighted and satisfied.

Child-*birth* and *nursing* have become the dread and horror of the votaries of fickle fortune, whose gods and goddesses live only in the present.

The great physician should and will stand forth in the true light of the science of his profession as the promoter of health and happiness, and the protector of family life and professional honor.

The people love justice and fair play, and the lawyers and doctors who practice with fidelity the great principles of their profession *must* be honorable in their relations to each other and the community at large. As the stars move in harmony with this world and the planetary systems, and reflect their light and beauty in the shadows of darkness, so do the true votaries of these great professions, in their intercourse and contact with struggling and wasting humanity, reflect the light, the glory, and the wisdom of their callings. And if we could only exclaim,

"Could a man be secure
That his days might endure,
As of old, for a thousand of years;
What things he might know,
What deeds he might do,
And all without hurry or care!"

By professional ethics we mean the science of duty as established and recognized in a system of principles and rules governing all licensed lawyers and doctors, and enforced and respected by high-toned and cultured gentlemen —a standard of professional honor so sacred and inviolate that no graduate or regular practitioner will ever presume or dare to violate it.

Can such a standard be established? We say Yes; and you ask How? In the profession of the law the courts are always open and ready to disbar any lawyer who is guilty of unprofessional conduct; and they can do it by summary process, as, in a recent case in Chicago, they compelled a shyster attorney to take down his sign and discontinue his advertisement of "*Divorces obtained with secrecy and dispatch.*" And similar ones have been discontinued in this city. May I suggest how this can be accomplished in the medical profession, so that glaring cards in the papers and distasteful and unprofessional circulars can be stopped and prohibited?

If the medical societies will provide in their codes of ethics that none such shall be recognized in the fraternity, and then some of the leading physicians of this city and State prepare a bill to be introduced in the Legislature providing for a medical commission, with power to sit, hear, and determine all grievances of that nature, and, in cases of guilt, to revoke licenses, and that no one shall be permitted to practice medicine without a license registered in the County Clerk's office, you will have a complete remedy against all the ills of *abortionists*, *quacks*, and *charlatans*. It is the sacred duty of good doctors to see that such remedies are provided at once.

These are times of needed reforms, and, if the great professions will inaugurate complete systems, we may look for better times in legitimate practice and a higher grade

of public morals and professional honor, and, with Hooker, agree that "of law there can be no less acknowledged than that her seat is the bosom of God; her voice the harmony of the world; all things in heaven and earth do her homage; the very least is feeling her care, and the greatest is not exempt from her power, though angels and men and creatures of what condition soever, though each in different sort and manner, yet all with uniform consent admiring her as the mother of their peace and joy."

Such law, properly enacted and wisely administered and enforced, will bring contentment, prosperity, and happiness.

Lord Brougham, one of England's most eloquent jurists, in advocating a great reform in her jurisprudence for the good and benefit of the people, inspiringly said:

"It was the boast of Augustus that he found Rome of brick and left it of marble; but how much more glorious will it be for that sovereign who can have it to say that he found law dear and left it cheap; found it the patrimony of the rich, left it the legacy of the poor; found it a sealed book, left it an open page and a living letter; found it the two-edged sword of craft and oppression, left it the staff of honor and the shield of innocence!"

Note.—A committee, consisting of Dr. Spitzka, the Hon. William Barnes, and Dr. McAuliff, was appointed by the society, to take into consideration the suggestions, and report at the meeting in October.

IS EXPERIMENTAL MEDICINE JUSTIFIABLE?*

By DUDLEY W. BUXTON, M. D., B. S.,
ASSISTANT TO THE PROFESSOR OF MEDICINE IN UNIVERSITY COLLEGE, LONDON; MEMBER OF THE ROYAL COLLEGE OF PHYSICIANS.

Gentlemen, I think it is. I go further. I say that medicine, whether it be a science or the empiric's art, is essentially experimental. This is a proposition I shall seek to prove to your satisfaction. I should say that some men reap the benefit, in their daily medical practice, of the experiment of others. They may not know this fact, having acquired their knowledge by the art of thumb-nail note-taking, but the fact remains. Some men learn their medical practice at the bedside. These men experiment.

Some men attempt to reproduce in their physiological research-rooms phenomena they find in clinical practice, and then strive to remove the morbid conditions; or, it may be, learn how, in the coming time, to protect men, women, and children from the lethal effects of a dread disease. These men experiment.

I hope to show you that, as the footsteps of medicine have traversed the sands of time, they have all along been guided by the staff of experiment, the light of inductive research. That staff, indeed, may have bent and grown warped when its fibers were overtaxed by headlong haste over rugged paths; but it is supple, it straightens itself, and saves the tottering load from falling. That light, too, may flicker, its luster may grow dim amid the scintillations of an *ignis fatuus* which we moderns call quackery, but it shines again bright and steady when it is taken into the darkness of the unexplored regions of the unknown.

With your permission I will state what I include under the term "medicine." I will define experiment, and will attempt to formulate the grounds which appear to me, by the common consent of civilized men, to be taken as sufficient for justification of an act.

Medicine, in this connection, I take it, implies a knowledge of the

1. *Causes* of diseases—ætiology.

2. The knowledge of how best to counteract these causes and so prevent the onset of disease—*i. e.*, state or preventive medicine.

3. The art of recognizing with what disease we are confronted—*i. e.*, diagnosis.

4. As well as the clear knowledge of the train of symptoms which will, in due order and course, supervene. It will be necessary to recognize not only that the disease runs such a course, and that at one particular time we may anticipate this or that emergency, but it is requisite that we should know what consequences may accrue from it, and, by due precaution, obviate the occurrence of the sequelæ. This includes clinical medicine in part.

5. We have yet to include the therapeutic treatment of disease, a branch of medicine of especial interest to us in this connection.

6. To anticipate the issue of a dangerous illness is also the business of medicine as an art. This, the practice of prognosis, has a most important bearing upon human happiness and prosperity. Such, then, is the scope of the science and art of medicine.

Experiments undertaken to further any of the aims and objects I have indicated above will constitute a portion of my theme to-night, and will have to be passed under your judgment, that you may say not, Is this or that individual experiment justifiable? but, Is the principle of applying the experimental method to medicine one which we, first as men, then as practitioners of medicine, can look upon as right and, in the highest sense of the word, legal? It is indeed hard to say what others will allow to constitute justifiability. It may not, indeed, be difficult to invent a wordy law, but this, gentlemen, is useless; old as the days of Butler was the truth that

"He that complies against his will
Is of the same opinion still."

I submit, then, that, for lack of a more comprehensive system of ethical morality, we may hold that those acts are justifiable which tend to promote the well-being of the greatest number. If a member of the intelligent and much-be-sat-upon minority claims attention to the sufferings of the few, with sorrow must I confess that his case is hard but hopeless. If the majority gain benefits from experimental medicine, I submit experimental medicine is not only justifiable, but its pursuit is an honorable duty.

Now, gentlemen, may I remind you that my task here commences? It is incumbent upon me to show that medicine has ever derived advantage from experiment, and, as practiced to-day, is being, week by week and month by month, enriched with new facts, established in sound gener-

* Read before the Medical Society of University College, London, March 4, 1885.

alizations, lopped of mushroom growth of unsound theories and practices of superstition, and that all this is due to the experimental method.

And here may I digress? I would have you to consider the ultimate uses of watch-springs and block-brakes as applied to mineral trains.

If the keen-eyed rhetorician, who is, I hope, ready to belabor my arguments and confute my contentions, should inquire what possible relation watch-springs and block-brakes have to experimental medicine, I would answer, Much in every way. Watch-springs are apt to uncoil with startling and unpleasing celerity when your escapement is out of gear, while brakes are used to stop or check progress. Philosophers tell us that the sum total of human progress is ever increasing, and men of genius, watch-spring like, hurry on this mental advance-guard. Here, then, comes into use the human brake—the Huns, the Vandals of days gone by, the anti-dissectionists of Vesalius's era, the anti-vaccinationists and anti-vivisectionists of the year of grace 1885—and enforces upon the pioneers thoroughness of work and readiness in intellectual combat. I regard the noble Attila, the Hun, and Mr. Hutton as most valuable persons, and daily return thanks for their institution? Can one, gentlemen, conceive any more appalling apparition than that of a man a century ahead of his neighbors? Lully only pretended to transmute copper into gold, but the indiscriminating inhabitants of Africa stoned him. Had he contented himself with the converse process, how great a demagogue he might have been!

Medicine has a long history; it is one which would bear out my main point of contention were it possible for me to bring before you its changing scenes and characters. It would best answer my purpose to permit the story of how medicine has slowly but surely advanced from the feudaldom of mere leechcraft to the epoch of reason which could produce a Laennec, a Louis, a Virchow, or a Jenner. It is a far cry from the mystic incantations of the priests of the Egyptian deity Isis to the systems of medicine which rest on the shelves of every practitioner of to-day; and so it will be impossible for me to do more than indicate a few of the main advances in medicine which have, as it were, marked epochs in the history of its philosophy. I will attempt this. I will strive to set forth how far these advances were due to the experimental method, and, in conclusion, I hope to lay before you the proposition which, coming last, is not the least important part of my argument.

It is difficult for us, who habitually compress into a meager curriculum of four or five years, the subjects which are kindred to medicine and surgery, to comprehend how deeply and inextricably interdependent are these sciences. It is hard for us to realize that in the old days men spent a lifetime in mastering those facts in anatomy which nowadays scarcely insure a student's passing his examination for the College of Surgeons.

Physiology, again, in spite of the work of such men as Vesalius, Servetus, Fabricius, and the long and illustrious roll of the Padua School, can not be said to have commenced until Harvey promulgated in 1619, before the Royal College of Physicians in London, the result of his experiments made three years anterior, and which proved to demonstration the circulation of the blood.

Comparative anatomy, the most important aid to the physiological physician, was studied earlier and more fully than human anatomy. Galen, who, from the pinnacle of the knowledge obtainable in the second century, could deride — which he did *con amore* — the mistakes of the older physicians, learned his anatomy and physiology from the dissection of apes. Nor is the reason for this far to seek. The ancients were as opposed to dissection of the human body as were our forefathers before the passing of the Anatomy Act, and apes in those days were held of little worth. Possibly the assent given to the evolution theory sways, and I think justly, the minds of antivivisectionists of this generation. It was not long ago that we were asked to consider how necessary to medicine is physiology. I am so thorough-going a believer in the absolute indissolubility of these sciences that I think the medicine of to-day is either physiology applied or it is quackery. So that if Galen and Harvey and their following learned their physiology from the story unfolded by experiments, I say these men used the experimental method to gain knowledge of the devious paths of medicine. It will at once be said that none nowadays object to the dissection of the bodies of defunct dogs and cats, or even of paupers. Provided the corses of honest men who die well to do, and of criminals, be respected, scalpel and scissors may run horrid riot as much as anatomists will. I may not pause to expose the shallow sophism of this argument. I will only say that anatomy is tolerated, being preferable to body-snatching, and that for my purpose I must be allowed to show that experiment, whether upon the cadaver or the living body, is equally important for a true knowledge of medicine.

Lizars, the well-known anatomist, dedicating to King George IV, says:

"It is impossible for me, or for any other teacher, in this department of professional education, not to regret, most painfully, that, through the increase of certain prejudices, as illiberal as they are alien to true philanthropy, obstacles are daily arising in your Majesty's United Kingdoms to the prosecution of anatomy. It is equally impossible not to believe, what ample observations demonstrate, that the magnitude to which they have already attained is, in its infallible and invincible operation, signally and seriously injurious to your Majesty's subjects, both in the public service and in all the ranks of private society. Many more of these than unsuspecting benevolence could have imagined are doomed, it were easy to prove, to a premature grave by the consequent deficiency in this requisite science on the part of those to whom the care of life and health is committed. And I will state most respectfully to your Majesty, in evidence of this alarming truth, well known and universally deplored as it is in the schools of medical learning, one circumstance of political importance enough, independently of humane considerations, to justify the freedom which I thus assume.

"In France, in Germany, and in Denmark the prosecution of anatomy is protected by their respective governments, and in them every facility is afforded for its com-

plete and satisfactory study. Hence, in great degree, it is of late years such of the medical youth among your Majesty's subjects as are enabled by their circumstances proceed to these foreign kingdoms in search of information of the most valuable kind, being compelled thereto by the dread of entering on the practice of their profession while ignorant of some of its fundamental principles, and of having, through the unavoidable fault of a merely British education, to collect, by repeated failures in their treatment of the living, that knowledge which they might have early and safely and ably acquired from intimacy with the dead."

These plates comprise within their range anatomy, physiology, and pathology, and what Lizars said of the study of the cadaver may well be repeated to-day of the study of physiological medicine upon the living organism. If experiment be eliminated from our methods, what will result? Instead of well-ordered and carefully planned trials, elaborated and calculated beforehand, and executed by hands deft in practice and ready of resource, we should have bungling and blind empiricism, *a priori* reasoning, and the havoc wrought of unrecognized experiments made by unskilled operators—operators, indeed, who may be serenely unconscious of the fact that they are executing experiments galore upon their patients. We will, however, return to this later on.

My next position is as follows:

To learn medicine we must adopt one of the following plans of study; that which is the best for the greatest number is, I venture to assert, the most justifiable. We must wait for inspiration and miracles; we must wait for accidents, such as when a bull gores a hole in some unhappy person's abdomen and establishes a gastric fistula, as occurred to Dr. Busch's patient, so enabling him to study the action of certain bodies upon the gastric mucous membrane; or, to take another "accident," we must observe the death agonies of some unhappy victim of rat-poison, and learn that strychnine produces tetanus; or (for a third course is open) we may prearrange certain conditions, and then observe the results of various alterations of such conditions—alterations likely prearranged and submitting themselves to our absolute control; we may, in fine, use experimental medicine. May I here again select an illustration?

I would choose the somewhat hackneyed case of nitrite of amyl. The drug was found to dilate capillaries, and hence to bleed the body into itself. The peculiar agony of *angina pectoris* being accompanied with harrowing spasm of the arterioles, was it not justifiable to employ nitrite of amyl for the relief of angina pectoris? I submit it was.

Now, of these three methods—which I will for brevity's sake call the (1) method by supernatural interference, (2) the method of accidents, (3) the experimental method—which is the best? Let us seek an answer in the experience of the past and the practice of the present.

The supernatural method is distinctly a prehistoric mode of going to work, but one that a certain prehistoric sect still extant in our midst confidently practice and preach. Most thinking men accept the wholesome tenet that the Almighty helps him who helps himself. Sir William Hamilton it was who adopted as his favorite aphorism,

"In the universe there is nothing great but Man;
In Man there is nothing great but Mind."

Hence may we, I think, fairly reason that man being endowed with a mind, points out that that mind should, in all humility, work out the ends of science and expect not inspiration and supernatural interposition in matters medical, although it may deeply and fervently be thankful if such unlooked-for aid comes.

There was a flourishing school of medicine in Egypt, over which presided a large sprinkling of demigods, and even the Egyptian Apollo graced the faculty with his company. The priests, male and female, were herbalists, but mainly relied upon superhuman aid. Herodotus said of Egypt: "Every place is full of doctors." Herodotus, had he lived a few centuries later, might, I think, have made the same remark of England. The institution of the school of Alexandria was subversive of the superhuman aids to medicine in Egypt. The accidents methods then came into vogue. All was vague and uncertain, for the method of experiment was as yet practically untried. I desire to avoid wearisome narrative; but it is worth your while, I think, to spare time and thought concerning the growth of medicine. It has convinced me of the justice of the cause I am defending, and I believe it will convince you also. We all know that the Jews were accomplished in many branches of physic. They, like many who flourish among us, believed in hygiene, and were often content with a happy diagnosis, leaving therapeutic details to take care of themselves. I have often heard, and not many miles from this building, the strange formula uttered: "Oh, give him a *placebo;* anything will do; and keep him under observation!" So, in my fancy, I can see the stately Levite, arrogant in his knowledge, diagnosticating "the emerods," "the botch of Egypt," "a withered hand," or "epilepsy," and then dismissing the "botch" patient with directions for a fig plaster. History repeats itself. Before I leave Egypt and Jewish physic lore I must say, in a parenthesis, that, in the first-named country, specialists were rife as now; even limbs and portions of limbs had their individual physicians! How long before a Rameses sits upon the throne of the Guelphs?

India, that profound enigma of buried civilization, knew medicine as she knew the most perfect system of philosophy, while Europe was in the most outermost of outer darkness. But even India seems to have leant solely on inspiration and accident for her medicine lore, and so she, too, never made any sensible progress beyond incantation and herbalism.

China was as inexact. Her physiologists thought that the human body was composed of water, fire, wood, metal, and earth. Even now I have heard it remarked that a common belief obtains that some portions of some human bodies owe their density to wood.

In Greece, medicine in the hands of Hippocrates is commonly held to have commenced its existence as a science. To his efforts in part we owe the first step toward the emancipation of medicine from the espionage of metaphysics and religion. Hippocrates marks a most important epoch, and his mistakes have importance not easily overestimated in our discussion to-night. He used purgatives; he talked of

crises and the *vis medicatrix naturæ;* indeed, the practice was much the same as that of a far more recent medical luminary. But remember, Hippocrates only experimented upon his patients. This he did freely, and cured many. He has, however, as far as a somewhat hasty search has assured me, omitted to put upon record his rate of mortality.

Confessedly a successful practitioner, he failed to lead the oncoming generations in the right way; he taught his humoral theory because his hands knew not the methods of research and his mind was warped by incomplete observations; therefore Hippocrates hindered the progress of scientific medicine for centuries. I have lingered here to show that, for lack of scientific methods of research, a transcendent genius went utterly astray. More than two thousand years have sped since Cos begat her philosopher, and are we endowed with more colossal brains than his? can we afford to throw away methods of which an Hippocrates stood so sorely in need? As the natural upshot of Hippocrates's transgression of his own canon—that no theory should be accepted unless based upon the most reliable of observations—his disciples for generations accepted his conclusions with a faith worthy of a better occasion. For centuries to come medicine was not; herbalism rose rampant, while slowly but surely was growing the foundation of a scientific basis for medicine.

Anatomy was prosecuted with more or less exactness. However, the main object of the physicians of those days was to show how futile was the teaching of their brethren, how ridiculous their practice. How different from the faculty of to-day!

"Blest, thrice blest, the Roman
Who sees Rome's brightest day."

And, as far as medicine is concerned, Celsus was blessed thrice, for it can not be said to have been extant until he undertook its exposition. All, however, who have read Celsus, although impressed by that great man's acumen and remarkable power as a clinical observer, will not fail to find in his writings a great want. Celsus knew naught of physiology; his wildest dreams never carried him beyond the method of experimenting upon his patients. With Celsus may be said to close one epoch, and with Galen to commence another. I have already traced the onward progress of physiology and anatomy through the very dark times of the mediæval ages; it yet remains to learn whether medicine, an older science, had advanced beyond these. Clearly if medicine be a science which can be studied independently of experiment, it should have advanced as facts were observed and classified. But medicine not only made no advance; it even retrograded. Men were for the most part more anxious to kill one another than to cure. Among the Arabs the lore—for we can not give it a more dignified epithet—was cherished.

I am coming now to Saxon medicine, a science somewhat behind what we would have it, but not one whit less fantastic than the practice of him who refuses to avail himself of scientific methods of research. I will offer a few excerpta from a quaint old book called "Leechdoms, Wortcunning, and Starcraft of Early England." For fever it is recommended that a long (? canine) tooth of a black dog be applied; or, failing this, recourse was to be had to a live wasp, which insect it was requisite to tie to the fever-stricken patient's person. Among hæmostatics was the following incantation: "Stupid on a mountain went, stupid, stupid was." Again, colic, we are told, yielded at once to the thrilling words uttered in a low tone: "Stolpus tumbled out of heaven." I do not know who Stolpus was, and, having never tried the remedy, I can not vouch for its success. It would be tedious to wade through more stuff of this sort; we may understand in what the practice of physic consisted in those days, and we can see that in it is another example of how medicine fares when dissevered from experimental research.

Strange companions was poor Dame Medicine to have before she attained her majority—an epoch I place at the time when men wittingly commenced to introduce the scientific spirit of experiment and research into her service. In the seventeenth century medicine was a puny child, supported and overruled by astrology. The science was simple in theory. Herbs were used largely, but only by him who knew the stars in their courses, and had, by toilsome watching and coquetting with the black art, learnt what times and seasons were opportune for each simple. I give the following as an example:

It is "good to purge with electuaries the moon in Cancer, with pills the moon in Pisces, with potions the moon in Virgo," etc.*

The book from which I quote was published only one year before John Evelyn wrote in his "Diary": "16th July. There died of the plague in London this week 1,100, and in the week following above 2,000."

But light was breaking. The alchemists, whose writings are so fascinating from their plausible plans of performing impossibility, were breaking the ground for chemistry. In 1774 came Priestley's discovery of oxygen, and from that date we may trace the steady, if slow, progress of medical chemistry. From hence the test-tube and the crucible were called into requisition as exponents of the probable action of drugs in the human body. But even such learned pedants as Elias Ashmole (1681) were credulous, for I find him curing his ague as follows: "April 11th. I took early in the morning a good dose of elixir, and hung three spiders about my neck, and they drove my ague away. *Deo gratias!*"

Harvey, as I have said, by his experiments actually broke up the systems of previous medical thought, all more or less erroneous, because based upon *a priori* grounds. The inventors of these systems were innocent of experimental methods of research, and hence, when Harvey dared to fly in the face of their pet theories, they declaimed him as infidel and madman. It was as in the story of Galileo. The earth did move and the blood did circulate. Malpighi, looking down the tube of his microscope, a poor enough affair but inexpressibly precious to him, saw little discs rolling and tumbling along. "Eureka!" he cried; the glorious theory was visible to the eye, and seeing was believing.

* "The Husbandman's Practice or Prognostications Forever," 1664.

Then the escapement gave way; mad, reckless experiment followed. Transfusion was practiced to an absurd extent. Stories are numberless of criminals resuscitated and the dead speaking. Even after such an impetus as Harvey's grand work gave, medicine made little progress. An age of unreason as bad as that of the astrologers followed upon the Paracelsian and chemical epochs. Newton's vast genius caused all the lesser lights to gravitate toward him, and led them to regard all the universe and its workings through mathematical spectacles. Those who, by a fine flight of fancy, deemed themselves physiologists, reduced that science to one of pure numbers. Each organ was duly calculated up, and its functions converted into logarithms. The heart was said to execute its movements by dint of a force of 180,000 pounds—that is, with the force of a small locomotive engine.

At this time the experimental method was being pushed by men whose names still linger in our midst and impart some element of historic interest to our hand-manuals, which, little thanks to the crude hurry of this generation, are usually written in as cut-and-dried and uninteresting a way as ever quill-driver could execute. Now flourished Lower, Malpighi, Bartholin and Steno, Swammerdam, John Mayhew, Raymond Vieussens, John George Wirsung, and Thomas Wharton, with Thomas Willis and Francis Sylvius. These names should be coupled with Glisson's, Scherner's and many others.

Sydenham, called England's Hippocrates, seems to have done little experimental work save in the domain of therapeutics. His clinical descriptions will, if you ever care to shake off the lethargy which induces so many of us to forget that we belong to an historical profession and should know its history, reveal how accurately he observed and how truthfully he delineated. Time, however, presses, and the story lingers mid many shallow places—shallows of thoughts and depths of ignorance.

The theory of Stahl need not detain us; he taught that the bodily necessities of the organism were presided over by the soul. Hence he advised an expectant treatment (this was the origin of the term), and sought to provoke the soul into reacting remediably upon the body. This, of course, is practically an excrescence from the supernatural system. Stahl, as one would expect, opposed the use of opium and cinchona bark, and pushed tartar emetic and the cupping dish.

Cullen it was who, collaborating the systems of Boerhaave and Hoffmann, reduced physiological phenomena to varying motions. The derangement in these internal movements normal to an organ constituted disease.

Cullen was confronted by Dr. John Brown, one of the ablest exponents of a hopelessly ridiculous system of therapeutics that ever retarded the progress of medicine. To his philosophy, disease was dynamic or sthenic and asthenic. His diagnosis, necessarily as often faulty as accurate, was followed by bleeding and purging to the *n*th, or stimulants pushed to a barbarous extreme. Dr. Erasmus Darwin next comes to point the moral of the preceding narratives. Like the humoral theory of Hippocrates, Stahl's, Hoffmann's, and Brown's each rushed headlong into a perfect quagmire of folly and illogical hypothesis, and all this arose from the fact that these men formulated theories, as ladies make patchwork quilts, from fragments left by others. Darwin, in spite of his bombast and inconsistency, was enabled to set these men right, because he, going to the fountain-head of knowledge, direct experience, showed by his own experiments that many of the premises upon which his predecessors based their theories were untenable.

William and John Hunter are worthy names to mark an epoch, and I need no evidence more emphatic than theirs in support of the proposition which stands at the head of my paper. With John Hunter there lived in the ties of the closest friendship one called Dr. Edward Jenner. The two Hunters and Jenner did more toward establishing the science of medicine than perhaps any triumvirate of contemporaries before or since. John Hunter tells us in very plain English that "my brother William" and I did experiments upon living animals. William Hunter's work upon absorption, in itself and through the subsequent research it excited, has produced results of the last importance to practical physicians. John Hunter's name is indissolubly united with the experimental method; nor can we esteem highly enough his colossal advances in comparative anatomy and physiology. One of his biographers records of him that he esteemed surgical as second to medical aid, "for," he said, "if we have to mutilate a body, which we do when we assume the knife, we fail in the primary object of our treatment to effect a cure."

Of Jenner and the introduction of vaccination what shall I say? To my mind, Jenner, the experimenter, stands out in glorious relief against the dark background formed by his detractors. Some will say that vaccination is not an unmixed blessing. Let us be open to conviction; but we should also remember that there are persons who conceive the earth is a flat surface; are such theorists to be treated as reliable?

Vaccination, involving as it did the whole theory of attenuation of morbific virus, as well as the practice of protection by the use of such attenuated virus, has opened a new research field, and one promising a most ample harvest. It is not too much to say that to Jenner we owe countless precious lives and happy homes; yet this man was an experimenter! Was he not justified?

And now we have passed the most barren part of our history and come upon times when men began to recognize the necessity of treating medicine from the standpoint of science. Floods of light began to be flung upon every page of medical lore. The pathologist no longer spoke in terms of a humoral theory; ceasing to waste time over spirits pervading nerves, he adopted the plain and only safe method of seeing first and believing afterward. Physicians passed beyond herbalism and began to inquire how disease could be explained and how treated upon rational principles. It is not necessary, nor does time permit me, to carry my narrative further. All who are here will readily in his own mind fill in the hiatus. I have attempted to trace the series of circumstances which led up to the introduction of the scientific method in medicine; that task accomplished, it will be not difficult for you to pursue the subject and determine

how far each subsequent observer increased knowledge by experiment and fortified clinical experience by an appeal to direct fact.

We have—I hope not too laboriously—waded through what has been done in the past by way of promoting the advance of medicine. We have seen that that advance has been made by the experimental method, and it has been open to us to appreciate a further fact—that when medicine has touched upon theoretical ground, unsupported by experiment, she has only too often been obliged to retrace her steps. The present aspect of the question has yet to be confronted. In our every-day practice we shall meet with diseases which are grouped according to our nosological systems, but which will, more or less, resist our book methods of treatment.

What are we to do?

Again, we shall daily learn the force of a great truth—that what our books teach us is inapplicable, is even false, when applied by the rigid law of rule of thumb.

What are we to do?

Those of us who care for more than hand-to-mouth work, and certainly those who care for successful treatment, will awaken then to know that all their true learning of medicine has yet to be accomplished, and has to be gained at the bedside of the patient. Nature will give them the problem ready for solution; the answer they will arrive at by themselves.

We shall, each of us, adopt one of two methods: We shall follow, as nearly as we can, in the steps of our teachers, and test, as far as we can, the truth of their statements concerning diagnosis and treatment upon our patients; or we shall soar farther and try fresh departures in diagnosis and treatment. The first method—the more usual one—is still an experimental one.

It will appear to you as clearly as the sun at noon-day that every time drugs are given, baths or what not applied, an experiment is performed, and the success of your treatment will depend upon the accuracy of your diagnosis and the proportioning of your doses. Take the B. P. If any one blindly follows its doses, do you think he would cure any one? The B. P. dose-list is a literary cow-catcher, instituted with the hope of preventing toxic doses being blindly given. No; you must give not only not an excessive dose, but equally important is it not to give an inactive dose. A friend of mine, when salicylates were not so commonly given as now, complained to me that his experience of willow bark was most unsatisfactory. He had seen the salicylism following full doses, and hence had given gr. iij three times a day. Acute rheumatism proved too much for him.

What are we to do? Our B. P. gone, we can only hang upon the lips of our teachers and hunt up stray prescriptions amid our manuals; failing these, we must search for tips in current treatises. No, I venture to say, none of these will suffice; you must learn how to experiment and push your remedies; you must do that which, until it is explained, seems so unhallowed and so cowardly; you must make your patient the subject of an experiment.

Now, see, there is no help for it; you will either experiment when you don't know it (and woe be to your patient), or, armed *cap-a-pie* with therapeutical lore, you will give him the best chance of benefiting from your skill. Now we go a step farther. All modes of treatment are based upon some general basis or ground for action, and it happens often enough that fresh departures in these modes of treatment seem demanded. Take an example. A large experience of fever showed that if the skin were cooled and its discharges removed, the well-being of the patient was insured. Cold water laved over head and arms gave relief; it was determined to try the cold bath. If you have seen—as some of you doubtless have—cases of hyperpyrexia, you will bear me out when I say, to me no case is so terrible, no patient wrings more one's heart-strings, than does the subject of that frightful condition. Is the cold-bath experiment justifiable? I believe yes. I have seen patients stricken with typhoid fever whose temperature, running up, has demanded heroic treatment. I have seen in some cases these poor people scream with fear and horror as they were lowered in the bath, and yet when they have been replaced in bed they have sunk into refreshing sleep and have rallied. That experiment was, I think, justifiable. If in the first cases of hyperpyrexia, the first cases of typhoid fever, the patients had died in spite of the bath, what would have been said?

Again, take drugs. It is a fact that many plants alike in botanical characters show a kindred action upon disease. To determine whether such is so in any case we have two plans to administer the drugs—to animals or to patients. The former method is highly deceptive, and can only be employed tentatively and as a preliminary to the administration to human beings. We are here discussing only the broad principle; there are many by-issues. The danger of the drug, the severity of the symptoms, would, of course, enter largely into the question of justifiability. In the cases above mentioned we have argued upon the question, Is it justifiable to experiment upon patients for their own good? and I have answered in the affirmative. What shall be said concerning the further question, Is it justifiable to experiment upon a man for the good of the community? Here I must adopt another answer. I should say that, at least as far as therapeutic research is concerned, the broad principle upon which we must work involves a negative answer. That there are exceptions I should be ready to admit; that researches which could involve neither risk nor ultimate inconvenience might justifiably be made I am prepared to believe. These cases I should expect would rest each upon its own merits. But that experimental therapeutics is justifiable when contingent dangers and inconveniences are fully put before the persons to be the willing subject of such experiments, I hold needs no championship of mine. Enough, I think, has already been said to show more than amply that the only true progress on the therapeutic side of medicine will occur as the outcome of such experiment.

Yet another side of this question has to be considered—one which ranks high in importance. To the few it occurs to learn medicine from observations of its results. In the dead-house, with scalpel, with microscope, with chemical test-tube, the scientist elaborates there a pathogenesis

which, with logical mind cultured in clinical records, leads him to a rational theory of disease. Now, to complete the chain of his reason, he needs to be able, by employing known morbific influences, to induce in his patient the pathological lesions he has seen and dissected. I can hardly take better instances than those of Ferrier's, Schafer's, and Horsman's experimental work upon brain areas; or, again, the last-named observer's splendid results in myxœdema.

The whole range of miasmatic and infective diseases, tuberculosis, splenic fever, chicken cholera, rabies, and perhaps we may add cholera, all have been elucidated, arranged, and brought within the scope of things understandable by experimental methods. It can not be said that these diseases have as yet been rendered amenable to treatment, but much has been done, and Pasteur has given earnest that in the future much may be done to obviate their occurrence. And, gentlemen, prevention is better than cure.

A CONTRIBUTION TO THE PATHOLOGICAL HISTOLOGY OF ACUTE AND CHRONIC CORYZA.*

By JOHN N. MACKENZIE, M. D.,
BALTIMORE.

In the "Philadelphia Medical News" of October 4, 1884,† I gave an account of the changes found in the different stages of intra-nasal inflammation, which was based upon the anatomical study of a large number of neoplasms removed from the nasal passages by means of the cold-wire snare. The object of the present communication is to call attention to some additional points in the pathological anatomy of that affection, which I trust may prove of general interest, both from a clinical and histological point of view.

The first specimen that I submit to your examination (Fig. 1) represents the microscopical appearances of a section through the inferior turbinated body of a man dead of Bright's disease, the result of long-standing mitral regurgitation and insufficiency.‡

Among the ordinary visceral changes usually found in such cases there were traces of old infarctions in both kidneys and spleen. The nasal passages presented the appearances commonly observed in the condition known as coryza, and in the permanent puffy condition found in more chronic inflammation, the most noticeable being intense engorgement of the cavernous tissue, especially well marked over the lower half of the middle and posterior portion of the inferior turbinated body. Upon cutting into the engorged bodies with a scalpel, the blood, which flowed freely, could be squeezed from them as water from a sponge. The mucous membrane of the maxillary sinuses was not in the slightest degree tumefied, and presented simply a more or less cyanotic appearance.

Under the microscope, the condition which at once attracts the eye is the enormous dilatation of the erectile spaces and the extreme tenuity of the intercellular walls. Here and there rupture of the latter has occurred from the enormous blood pressure, and two or more spaces in this way communicate. Along the inner walls of the dilated spaces are seen congregations of lymphoid corpuscles, and in some of them collections of fibrinous exudation.

The mucous membrane proper presents no noticeable pathological change. The epithelial layer is intact. At some places it seems slightly thicker than at others, but, beyond a moderate amount of cellular infiltration of the tissues beneath the basement membrane, there is nothing in the mucous layers to call for special remark.

Jutting out from and attached to the wall of the central sinus (in the diagram) is a well-formed parietal thrombus, to which I would like to call particular attention.

I bring this case before you for discussion as one of peculiar interest, for it is instructive in many ways. So far as I am aware, the histological appearances in acute coryza have never been investigated. In this specimen we have the probable microscopical picture of that disease. Here, too, is illustrated the minute anatomy of the puffy condition or state of permanent dilatation of the erectile spaces which characterizes the second period of the simple inflammatory stage before hypertrophic changes have developed, and to which I have called attention elsewhere.*

Fig. 1.

* Read before the American Laryngological Association, June 25, 1885.

† "Some Notes on the Pathology of Intra-nasal Inflammation."

‡ I am indebted to Dr. W. T. Councilman, Associate in Pathology in the Johns Hopkins University, both for the beautiful section and notes of the post-mortem examination upon which these remarks are based, and for the accurate drawings which illustrate the text.

* See article referred to, and also a paper in the "Medical News" of April 4, 1885, entitled, "Notes on the Classification, Diagnosis, and Treatment of the Stages of Chronic Nasal Inflammation."

Of great interest, too, is the formation of the parietal thrombus, as illustrative of a mode of obliteration of the erectile spaces heretofore unrecognized.

In connection with the negative post-mortem appearances found in the maxillary sinus I would like to offer some suggestions on the relation of inflammatory affections of that cavity to intra-nasal processes.

While I am convinced that the chronicity of certain forms of nasal disease, the persistency of a fair proportion of neuralgic (and other reflex neuroses) affections of the head and face, are traceable to latent or unsuspected chronic antral inflammation, while it is doubtless true that affections of the maxillary sinus often run their course unrecognized during life, the *secondary* implication of that cavity in acute and chronic inflammatory processes originating in the nasal passages is, comparatively speaking, rare.

Inflammation of the maxillary sinus may result from congenital or acquired defect of the naso-antral aperture, or from its closure by the swollen and hypertrophied nasal tissue, polypi, crusts, etc., conditions which may favor the retention and decomposition of the antral secretion. Inflammation from this cause, however, occurs less frequently than is universally taught by inference from purely theoretical considerations. I base this assertion not only on clinical observation, but also on the results of post-mortem investigation. Those of you who choose to investigate the anatomical aspect of this question will be amazed to find how infrequently the mucous covering of the sinus participates in the inflammatory condition of the nasal fossæ. It is the rule to find the most marked hypertrophy of the nasal tissues, and even complete atrophy, associated with a normal condition of the sinus. What is the explanation of this fact?

On the nasal aspect of the naso-antral opening is a duplicature of the erectile tissue of the turbinated bodies, which in all probability serves the useful purpose of excluding from the cavity of the sinus, by means of the anatomical barrier involved in its erection, various irritants derived from the external world and nasal passages. This tissue ceases abruptly at the antral aperture. On the other side of the opening lies the peculiar loose, vascular membrane of the sinus. In the majority of cases this zone of erectile tissue constitutes the extreme anatomical limit of the nasal inflammation. The thin, loose, serous-looking membrane of the sinus differs essentially from the nasal mucous membrane, and especially that portion which surrounds the entrance into the maxillary sinus, and the abrupt transition of the one tissue into the other would therefore militate, on theoretical grounds, against extension of the inflammatory process into the antrum. In other words, I believe that the so-called extension of inflammatory action from the nasal passages to the antrum—the secondary inflammatory implication of that cavity—is of comparatively infrequent occurrence; and that, when inflammation of the sinus from extension is assumed, the condition will be found, on post-mortem examination, to be one of simple congestion, with possibly some accumulation and retention of the antral secretion from mechanical causes. Even if the amount of secretion be temporarily increased, the great power of absorption possessed by the membrane of the sinus will usually suffice to make it a matter of secondary importance.

I am inclined to believe that too much stress is laid upon the decomposition of antral secretion as a factor in the production of inflammation. Take, for example, a simple coryza. With the general erection of the turbinated tissues the orifice of the antrum is completely closed, congestion follows, with possibly an increased secretion of the antral fluid. Whether this secretion, thus hermetically sealed, so to speak, in the antrum undergoes decomposition before the patency of the opening is restored and the air gains admittance, is questionable; but, on the other hand, that decomposition does occur is beyond dispute, for, when the swelling from the acute rhinitis subsides, the aperture becomes free and, in some instances, the fœtid antral secretion is discharged into the nasal passages, a fact which accounts for the peculiar fœtor of the expired air from the nostrils which is sometimes observed at the close of a severe coryza.

In the second specimen (Fig. 2) are shown the microscopical appearances in the hypertrophic stage of chronic nasal inflammation before complete obliteration of the erectile spaces has taken place. Contrast the condition here

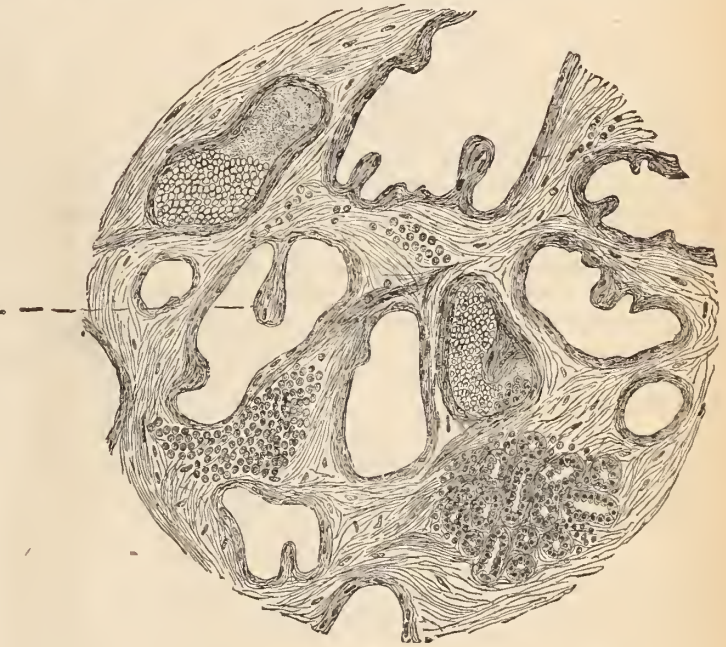

Fig. 2.

with that found in the first specimen and in the acute and earlier stage of chronic rhinitis. Observe closely the little buds or bulbous processes which jut out from the walls of the cavernous sinuses, and which are made up of outgrowths from the newly formed intercellular connective tissue. In my anatomical study of this stage I overlooked these little buds, and my attention was subsequently called to them by my friend, Dr. Councilman, who had taken one of my sections for examination.

Projecting inward, they form bulbous processes or septa of varying thickness, which sometimes interlace, sometimes form bands which connect one portion of the sinus-wall with another, thus constituting another factor in the division and obliteration of the cavernous spaces.

Care should be taken not to confound them with the remains of a thinned and ruptured intercellular wall; in the latter case a similar projection will usually be found at a point diametrically opposite to that occupied by the projecting band.

We have, then, four modes of obliteration of the erectile spaces in nasal inflammation:

1. By the contraction of the newly formed intercellular fibrous bands.

2. By obliteration of their lumen by masses of round cells which resemble the white corpuscular elements of the blood. (See first article in the "Medical News.")

3. By the formation of thrombi in certain cases.

4. By the process of septa formation.

Book Notices.

The Ear: its Anatomy, Physiology, and Diseases. A Practical Treatise for the Use of Medical Students and Practitioners. By Charles H. Burnett, A. M., M. D., Professor of Otology in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. With One Hundred and Seven Illustrations. Second Edition, Revised and Rewritten. Philadelphia: Henry C. Lea's Son & Co., 1884.

The first edition of Dr. Burnett's work, published seven years ago, was in every way worthy of the kind reception accorded it, and it has been a matter of surprise to many workers in the field of otology that so long a period has elapsed before the appearance of the second edition. The science of otology has in this period made very rapid advances, many of them of an exceptionally practical character. These have made necessary many alterations in the first edition, and some of the chapters have been practically entirely rewritten. The result appears in a handsome volume of nearly six hundred pages, printed in large, clear type on good paper, and with numerous illustrations in the text. Large additions have been made to the text, especially in the articles on Abnormities of the Auricle, on the Treatment of Chronic Otorrhœa, and the subject of Aural Polypi. The arrangement of the chapters is much the same as in the first edition, about two hundred pages being taken up with a description of the anatomy and physiology of the ear, and a discussion of the theory of sound and hearing, and the method of the examination of patients. There is a very satisfactory presentation of the subject of otomycosis and its treatment by the insufflation of germicide powders. There are some interesting pages upon Organic Disturbances in certain Diseases of the Middle Ear. The chapters on the Treatment of Chronic Purulent Inflammation of the Middle Ear and on the Course and Consequences of Chronic Purulent Inflammation of the Middle Ear are excellent, and throughout the entire work may be noted the painstaking care of the author in bringing the second edition abreast with the advances made in otological science up to the present time. From a careful perusal of the work in its new dress, it may be seen that the second edition is as worthy of a welcome reception as the first one was.

BOOKS AND PAMPHLETS RECEIVED.

A New England Conscience. By Belle C. Greene. New York: G. P. Putnam's Sons, 1885. Pp. 196.

Report on the Mortality and Vital Statistics of the United States as returned at the Tenth Census (June 1, 1880). By John S. Billings, Surgeon, United States Army. Part I. Washington: Government Printing Office, 1885. 4to, pp. lxiii–767.

Comparative Anatomy and Physiology. By F. Jeffrey Bell, M. A., Professor of Comparative Anatomy at King's College. Illustrated with 229 Engravings. Philadelphia: Lea Brothers & Co., 1885. Pp. xii–555.

Diseases of the Tongue. By Henry T. Butlin, F. R. C. S., Assistant Surgeon and Demonstrator of Practical Surgery and Diseases of the Larynx, St. Bartholomew's Hospital, etc. Illustrated with Chromo-lithographs and Engravings. Philadelphia: Lea Brothers & Co., 1885. Pp. viii–451.

Elements of Modern Medicine; including Principles of Pathology and Therapeutics, with many useful Memoranda and Valuable Tables for Reference, etc. Designed for the Use of Students and Practitioners of Medicine. By R. French Stone, M. D., Professor of Materia Medica, etc., in the Central College of Physicians and Surgeons, Indianapolis, etc. New York: D. Appleton & Co., 1885. Pp. xiv–368.

Second Report of the State Board of Health of the State of Tennessee, October, 1880–December, 1884. Nashville: Albert B. Tavel, Printer to the State, 1885. Pp. xv–600.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & Co. Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 22, 1885.

THE BRITISH AND THE AMERICAN MEDICAL ASSOCIATIONS.

BETWEEN the American Medical Association and its really great prototype, the British Medical Association, about as much resemblance may be traced as between "Punch's" little India-rubber effigy of the First Napoleon and the statue of Julius Cæsar, in the cartoon which represented Louis Napoleon vigorously inflating the former and remarking to the statue of the great Roman: "Aha, monsieur, I shall soon make him so big as you!" Faint as the likeness is, however, between the two associations, and rapidly as even the most ambitious aspirations of our American organization are being crushed out of it by mismanagement, it may not be amiss to reflect upon some of the difficulties which beset large bodies of men banded together, in spite of clever management. But, first, in order to set forth more precisely one phase of the difference between the British and the American associations, we will quote from certain comments by the "Medical Times and Gazette," of London, on the affairs of the British Medical Association. "The lamentable muddle into which the sister association in the United States has thrown the medical profession in that country," says our contemporary, "has come upon us as a revelation, to make us grateful for the policy which has kept our own association free, on the whole, from the machinations of self-seeking wire-pullers, and has kept a sufficient place of honor for the scientific leaders of the profession. Reading of what has recently happened across the Atlantic, we ought to be thankful that the powers of our own association have not been abused, as they might have been, to the forcing upon us of leaders whose only claim to leadership is skill in the lobby. An association, again, which can tolerate homœopaths upon its roll contrasts very favorably, in respect of discretion and liberal feeling, with one which, like the American association, ostracizes regular practitioners simply for claiming the individual liberty of holding consultation with whom they please."

But the "Times and Gazette" confesses that it can not help feeling that the success of the British association is "a little hollow," and it proceeds to show the great degree to which the prosperity of the association depends upon the excellence and the acceptable character of its publication, the "British Medical Journal." The article then goes on, in a manner most creditable to the journal in which it appears, to call attention to the pre-eminent ability of the editor of the "British Medical Journal." But the "Times and Gazette" hints that the very mainspring of its present prosperity, its journal, may yet prove a stumbling-block to the association. It fears what may happen with the journal in other hands, and states its conviction that the association "can not be declared to be an assured success until it has weathered, once or oftener, a change in the editorship of its journal."

We have no doubt that any one familiar with the work of editing a medical journal will appreciate the solicitude felt by the "Times and Gazette," even in the case of any important journal, and doubly in the case of one that, like the "British Medical Journal," has to cater at the same time to the demands of its readers at large and to the special interests of the association of which it is the organ. If there is occasion for such a feeling of insecurity with regard to a journal and an association both so well established as those in question, how much greater ground is there for guarding against the contingency of a change of editorial management in the case of the "Journal of the American Medical Association." That publication is still in its infancy; yet on more than one occasion efforts have been made to take it out of the hands of its present editor—efforts which we have always regarded as unwise, and against which we have raised our voice from time to time. If a change in its editorship would be perilous at any time, it would be tenfold more dangerous at a time when the journal is still undeveloped, and the association itself in a condition that has called down upon it the indignation of hundreds who in the past have been among its most efficient supporters, and who are now unable to see any reasonable prospect of its soon resuming the honorable position which it occupied a few years ago.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 18, 1885:

DISEASES.	Week ending Aug. 11.		Week ending Aug. 18.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	14	4	23	6
Scarlet fever	8	2	25	4
Cerebro-spinal meningitis	2	1	1	1
Measles	16	2	31	3
Diphtheria	20	14	30	16
Small-pox	1	0	0	0

Yellow Fever in New York.—It is reported that, on Wednesday last, a sailor, recently arrived from Cuba, was found in a hall-way, in the lower part of the city, suffering from yellow fever.

Anthrax in Illinois.—A disease, said to be of the anthrax variety, is prevailing among the cattle in the neighborhood of Bloomington.

The Health of Chicago.—The "Condensed Statement of Mortality" for July, published by the Health Department, shows that there were 16 deaths from measles, 12 from scarlet fever, 31 from diphtheria, 13 from croup, 14 from whooping-cough, 2 from typhus, 79 from typhoid fever, 15 from cerebro-spinal fever, 19 from malarial fever, 456 from diarrhœal diseases, and 54 from other zymotic diseases. In 1884 the population, according to the School Census, was 630,000.

The Pension Board of New York City.—The Board of Examining Surgeons for this city has been re-organized by order

of the Commissioner of Pensions. The members of the late board were Dr. S. S. Burt, Dr. A. B. Judson, and Dr. W. C. McDonald. The new board is composed of Dr. W. C. McFarland, Dr. Ira Wilcox, and Dr. L. P. Walker. This action of the Commissioner is understood to be based on political grounds.

The University of Vienna. — The "Medical Times and Gazette," of London, learns from its Vienna correspondent that Prof. Bamberger has recently been elected Rector Magnificus of the university. This disposition of the honor, the highest in the gift of the university, is as much a compliment to the medical faculty as to the individual. The post is held for one academical year.

The American Dermatological Association will hold its ninth annual meeting at Indian Harbor Hotel, Greenwich, Conn., on Wednesday, Thursday, and Friday, August 26th, 27th, and 28th.

The International Medical Congress.—It is understood that the American Medical Association's new committee will hold a meeting in New York on the third of September.

The Death of Dr. Francis Ashhurst, of Mount Holly, N. J., took place on Monday, August 17th, in his forty-third year. He was graduated from the University of Pennsylvania, Department of Medicine, in 1867, and, in conjunction with his mother, founded the Burlington County Hospital at Mount Holly. He was a member of the Philadelphia County Medical Society.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 8, 1885, to August 15, 1885:*

Campbell, John, Colonel and Surgeon. Granted leave of absence for one month. S. O. 184, A. G. O., August 13, 1885.

Ives, Francis J., First Lieutenant and Assistant Surgeon (recently appointed). Ordered for duty in the Department of the Platte. S. O. 184, A. G. O., August 13, 1885.

Azpell, Thomas F., Captain and Assistant Surgeon. Retired from active service August 10, 1885. S. O. 181, A. G. O., August 10, 1885.

Chapin, A. R., First Lieutenant and Assistant Surgeon. Granted one month's leave, to take effect when service can be spared by commanding general, Department of the Missouri, with permission to apply for one month's extension. S. O. 179, A. G. O., August 6, 1885.

Wales, Philip G., First Lieutenant and Assistant Surgeon (Fort Cœur d'Alène, Idaho). Ordered for temporary duty at Boise Barracks, Idaho. S. O. 130, Department of the Colorado.

Appointment.

Kendall, William P., to be Assistant Surgeon, United States army, with the rank of first lieutenant, to date from August 12, 1885.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the two weeks ending August 15, 1885.*

Bailhache, P. H., Surgeon. To proceed to Delaware Breakwater Quarantine as inspector. August 15, 1885.

Stoner, George W., Surgeon. Granted leave of absence for thirty days. August 10, 1885.

Society Meetings for the Coming Week:

Monday, *August 24th:* Boston Society for Medical Improvement.

Wednesday, *August 26th:* Auburn City, N. Y., Medical Association; Berkshire District, Mass., Medical Society (Pittsfield); American Dermatological Association (first day—Greenwich, Conn.).

Thursday, *August 27th:* Cumberland County, Me., Medical Society (Portland); American Dermatological Association (second day).

Friday, *August 28th:* American Dermatological Association (third day).

OBITUARY NOTES.

D. Colden Murray, whose death at the New York Hospital on the 17th of this month has brought distress to a large circle of friends, deserves more than a passing notice in our columns.

If such men as he were more numerous in the controlling boards of our hospitals and educational institutions, the future of medical education would cause us no uneasiness. Single-minded, liberal, broad in his estimate of his fellow-men, discriminating, just, there are few to replace him in the ranks where many such are needed. He entered the hospital as a patient because of the advantages of the proximity of the surgeons. His malady was a sarcoma of the bladder, and the operation which was performed gave only temporary relief, which was all that could be hoped.

He was born at the country seat of his father, Robert I. Murray, at Coldenham, N. Y., on October 10, 1821, and comes from Revolutionary ancestry, being a great-grandson of Cadwallader Colden and John Murray, of Murray Hill, whose beautiful wife kept the British officers at luncheon while Washington was crossing the river. He was also a grandnephew of the grammarian, Lindley Murray. The foundations of an excellent education were laid at Haverford College, to which he went at the age of fourteen. He began his business life in the shipping house of De Peyster & Whitmarsh, in this city, and was afterward connected with the firm of Hussey & Mackey, ship-brokers, at No. 62 South Street. This firm was subsequently changed to Hussey & Murray, and still later to Murray, Ferris & Co. The latter firm operated a line of steamers to Savannah, which was known as Murray's Line. The firm also had an interest in a line to Cuba, and owned many sailing-vessels. In 1879 Mr. Murray retired from the firm, and has done no business since, but has devoted his time to charitable objects.

Besides being secretary of the Society of the New York Hospital, succeeding his father, who served from 1824 until his death in 1858, he was treasurer of the New York Dispensary from 1856 to 1884, a director of the Sailors' Snug Harbor, a director of the United States Fire Insurance Company, and was connected with other insurance companies. He was one of the founders of the New York Club, and continued a member of it until a short time ago. He was a member of the Union League and St. Nicholas Clubs. For many years he was a warden of St. Ann's Church, at which his funeral took place on Thursday afternoon, when the Rev. Dr. Gallaudet conducted the services. The burial was at Delhi, where live the family of his wife, who survives him.

His interest and his strong protecting arm have done service which should never be forgotten. To him the Training School for Nurses at the New York Hospital owes its existence and prosperity; to him the Pathological Department of that institution is under the greatest obligations; and his interest in the welfare of the patients and doctors in the Chambers Street Hospital, the Bloomingdale Asylum, and the New York Dispensary has been as untiring as it has been intelligent.

Many of our readers whose success in life has doubtless been in no small degree aided by a connection at some time with the New York Hospital will feel his loss most keenly.

Proceedings of Societies.

PHILADELPHIA CLINICAL SOCIETY.

Meeting of May 22, 1885.

The Vice-President, Dr. Amy S. Barton, in the Chair;

Mary Willits, M. D., Reporting Secretary.

Removal of a Lymphoma from the Neck; Recovery.—Dr. Susan P. Stackhouse reported the case of a woman forty years of age. Sixteen years ago she first noticed a small tumor just below the left ear; it caused no inconvenience except the projection of the ear-ring. On seeking medical advice, she was told that there was no danger attending the growth so long as it remained undisturbed. It increased in size gradually, and was attended with neither pain nor tenderness. The patient entered the Woman's Hospital of Philadelphia, and was operated upon October 17, 1884, by Dr. W. W. Keen. At the time of the operation the tumor extended from the ear to an inch below the cricoid cartilage, and was two inches and a half in width, its size affecting deglutition and respiration. The skin was not involved, but the veins were enlarged, and two pulsating vessels could be felt to enter the tumor. The growth was firm and inelastic, and movable to a certain extent.

After the patient was etherized, an incision four inches long was made, care being taken to avoid the external jugular vein, which crossed the growth. The hæmorrhage, which was quite profuse, was controlled by hæmostatic forceps and ligatures, it being necessary to ligate eighteen vessels. On account of the vascular nature of the growth, and its loose connections with surrounding structures, the adhesions were broken up with the grooved director. The tumor was intimately connected with the internal jugular vein for nearly three inches, and very careful dissection was required in order to preserve the integrity of that vessel. The wound was closed by wire sutures, after the introduction of a drainage-tube and a bundle of horse-hairs. The operation required one hour, and the patient became very much exhausted, but reacted very quickly after a hypodermic injection of brandy. The wound was dressed on the following day on account of there being considerable oozing of blood; the tube was then removed, the horse-hairs being left. After this the patient did very well; the temperature never reached 100° F., the only difficulty being some trouble in deglutition for three or four days. On the eighth day the dressings were removed scarcely soiled; the wound was closed with the exception of one small point. The patient was discharged from the hospital two weeks later.

Complete Retroversion of the Uterus from Distension of the Bladder.—Dr. Stackhouse also reported a case of this affection to which she was called July 22, 1884, it being said that the patient was dying. She found a woman, thirty-five years of age, with normal temperature; pulse 100, feeble and irregular; respirations gasping and rapid; face anxious and eyes injected. She did not complain of pain, but had a constant desire to urinate, and stated that she had passed urine repeatedly. Pressure upon the abdomen caused a slight flow of urine. The abdomen was greatly distended, the patient stating that the enlargement had existed for ten days, and had come on suddenly and without any previous illness. She did not think that she was pregnant. On examining the abdomen, its enlargement was found to be due to an oval, elastic tumor, extending from the symphysis pubis to within two inches of the ensiform appendix. It was regular in outline, and in no way resembled a pregnant uterus. An examination *per vaginam* showed that the tumor had no connection with the uterus, that organ being completely retroverted, the fundus being only a short distance from the vulval orifice, and the cervix behind the symphysis pubis. The uterus was somewhat enlarged and perfectly immovable. The patient insisted that she was not pregnant, and said that four months before her abdomen became enlarged suddenly, that she was unable to urinate, and that a large quantity of urine was drawn off by the catheter, which relieved her condition. A No. 16 (Fr.) male catheter was passed, and fifty ounces of very pale, clear urine were drawn off. The urine was neutral, with a specific gravity of 1·002, and contained a small quantity of pus, but no albumin. The relief was great, the respirations were no longer gasping, and the face lost its anxious expression. A soft-rubber French male catheter was passed into the bladder and kept in place by bands of adhesive plaster. The paralysis of the bladder was complete, and lasted for a week. It was found impossible to restore the uterus to its normal position by manipulation, and the patient was instructed to place herself in the knee-chest position for five minutes at a time frequently during the day. At the end of ten days she urinated without difficulty, and the uterus was restored to its normal position.

Asphyxia caused by a Plate of Artificial Teeth impacted in the Trachea; Death.—Dr. Louise S. Blum reported a case and said that the literature of the subject of foreign bodies in the air-passages was exceedingly rich in rare and peculiar cases of extreme interest. Almost every physician had been called upon, at least once in the course of his practice, to remove some article from the air-passages of a child, who had made the mouth, instead of the pocket, a common receptacle. In such cases there had been found and removed pins, needles, marbles, fish-hooks, rings, buttons, button-molds, pebbles, sticks, pens, slate-pencils, ears of rye, wheat, or barley, fruit-stones, seeds, and numerous other articles. It seemed that this reprehensible practice was not confined to children, for a number of the articles mentioned, as well as some others, had been removed in the cases of men and women. Buckley, for instance, removed a copper umbrella-tip from the larynx of a man; and, in two other cases on record, a puff-dart* and a hard rubber tube were similarly removed. Instances of pieces of the various kinds of food entering the air-passages during deglutition were of such frequent occurrence that they received no mention. The fact that tracheotomy-tubes and corroded pieces of the same, hypodermic needles and various surgical instruments, or portions of them, broken off during operations, also unsecured corks used for keeping the jaws apart, leeches carelessly applied, sponges, etc., had all been found at various times in the respiratory tract, was of far more importance and interest to the medical profession. It was scarcely less interesting to read that matters vomited during anæsthesia, or unconsciousness during apoplexy or epilepsy, as also regurgitated chyme, curdled milk, worms from the alimentary tract, pus from tonsillar, post-pharyngeal, or epiglottic abscesses, necrosed nasal, palatal, and cranial bones and laryngeal cartilages, had all at various times acted as foreign bodies in the air-passages of man. Even a lymphatic bronchial gland, one inch in length, had been known to cause death by becoming impacted in the rima glottidis during a violent fit of coughing. A still more remarkable case was that recorded by Ruehle in "Kehlkopfkrankheiten," in which the epiglottis of a man was drawn into the upper orifice of the larynx during deglutition, where it became firmly impacted, and, acting as a foreign body, caused death. During operations upon the teeth and mouth, one or more teeth or crushed fragments of the same had frequently fallen into the windpipe. More rarely a number of artificial teeth connected by a metal band had become

* See this Journal, November 1, 1884, p. 487.

dislodged during sleep, and had been drawn into the larynx or trachea by the attempts made at respiration. This accident had also occurred during deglutition, although in that case they were usually swallowed with the bolus of food and entered the stomach. Still more rarely had this accident occurred where the teeth were attached to a plate. The only case of the kind on record, so far as Dr. Blum knew, was that reported by Mr. Henry G. Croly, of Dublin, cited by Prof. Gross, in which instance seven artificial teeth, set in gutta-percha, were arrested at the junction of the larynx and trachea. The case which formed the subject of Dr. Blum's paper was a parallel one, but was far more peculiar than the majority of such cases were likely to be, from the fact that the accident occurred in the course of an acute disease, and was not suspected until after the death of the patient.

On February 18, 1883, the doctor was asked to call upon Caroline N., a widow, aged twenty-five. The patient was examined carefully; temperature 104° F., pulse 128. Two calls were made on the following day and the temperature taken in the morning and in the evening, which, with the previous history of the case, confirmed the diagnosis of malarial fever of the remittent type.

February 21st the temperature was 103° F., pulse 115. February 22d, temperature 102° F., pulse 110. Within an hour after the last visit Dr. Blum was hastily recalled to the patient, the messenger saying that she was dying of hæmorrhage. The patient, with livid face and convulsed, was being held down by four people, and as the doctor reached the bedside she gave a few gasps and expired before anything could be done for her relief. With the last gasp of the dying woman and the consequent dropping of the lower jaw the loss of the teeth was noticed by the mother, who called the doctor's attention to the fact; but a thorough search of the room did not reveal them. A history of the patient's condition and actions just prior to death convinced Dr. Blum that the teeth had become dislodged and had entered the air-passages, thus causing death. A post-mortem examination was made on the next day, and showed that the heart and lungs, otherwise normal, presented the usual signs of death from asphyxia. The liver was congested and softened; the spleen was softened and much enlarged, thus verifying the diagnosis of malarial fever. All the other organs were found in a normal condition. The missing teeth were found in the trachea about two inches below the larynx. The plate was of the usual size, of vulcanite, and had four teeth attached to it, and was so firmly wedged that force little short of violence was required to remove it. In the vigorous efforts made to dislodge the plate, one of the teeth, which was imbedded in the walls of the larynx, was broken off and left behind.

Meeting of June 26, 1885.

Dr. Charles K. Mills in the Chair.

Mary Willits, M. D., Reporting Secretary.

Carcinoma of the Uterus.—Dr. D. W. Barr reported a case in which the patient had resorted to the "Faith Cure." Early in January, 1879, he was called to see Mrs. S., forty-six years of age. She had been suffering at intervals for several months from severe uterine hæmorrhages. A vaginal examination revealed a cauliflower excrescence which involved the posterior and a portion of the anterior lip of the os; the vagina was not implicated. An operation was decided upon, and, in the presence of Dr. C. A. Groff and Dr. I. G. Heilman, the cervix uteri was removed close to the body by means of an écraseur. The wound healed kindly and without any trace of local trouble, and for two years and a half the patient's health was good, although she had mental forebodings. At the end of the third year some hæmorrhage occurred, and an examination revealed granulations of a specific character, apparently involving the entire endometrium. The whole surface was thoroughly cauterized with Vienna paste, and the symptoms were arrested for another year, making four years of vigorous health. Hæmorrhage again occurred, and an examination revealed a marked epithelioma involving the vaginal wall. The body of the uterus was enlarged and also evidently involved. Palliative measures were resorted to, but there was no hope of eradicating the disease. The patient was much alarmed, and, although there was neither pain nor hæmorrhage, she gave evidence of speedy dissolution. At this point she made arrangements for the "Faith Cure," sought the prayers of a circle and was anointed, after which she declared herself cured. Her general condition improved, and when Dr. Barr met her three months later he did not recognize her, because of the improvement in her appearance. Her health seemed good for about a year, when she again began to fail, and he was called to see her, after a day of severe suffering. He found a distended bladder, which was relieved by the catheter. An examination showed that the cancer had never been healed nor its progress in any way arrested, but that it filled the pelvic cavity, and the enlarged uterus reached above the umbilicus. This increase in size had taken place in about two years, the growth having steadily progressed notwithstanding the patient's apparent good health. She died soon after. The tumor in itself was painless through the entire period of its growth, death being induced chiefly from its pressure upon the neighboring vessels, firm adhesions having formed between the two.

Dr. Charles P. Turner said, in referring to the "Faith Cure," that he had known of several cases of nervous inertia that seemed to be cured by the influence of a strong will over a weak one, but the benefit was transient. He would believe in the "Faith Cure" when he saw a case of tuberculosis or cancer cured by that method.

Dr. E. E. Montgomery said that the class of cases the cure of which would convince one of the efficacy of the "Faith Cure" were the very ones that were not treated in that way. He instanced the case of a lady with organic disease of the heart who applied for treatment by this method, and was told that her case was not a suitable one for that form of treatment.

Reports on the Progress of Medicine.

OTOLOGY.

By CHARLES STEDMAN BULL, M. D.

Disease of the Nervous Apparatus of the Ear.—Kipp ("Arch. of Otol.") reports three cases presenting, in connection with Ménière's train of symptoms, certain uncommon features. The first case was that of a man, aged forty-eight, who had been totally deaf in his right ear since infancy. In this case Ménière's train of symptoms had been preceded by a febrile paroxysm and followed by neuralgia and erysipelatoid inflammation of the ear. The case resulted in partial recovery of hearing. The facts that the hearing of the left ear was very acute before the initial chill and that absolute deafness was rapidly developed without the slightest objective signs of disease of the middle ear make it tolerably certain that this case was one of primary disease of the nervous apparatus of the ear. The process was probably inflammatory, which started in the cerebral meninges at the base, and thence spread to the labyrinth and afterward to the Gasserian ganglion. This view of the probable seat of the disease is strengthened by the fact that the hearing for speech was partially restored, while deafness for low tones remained.

The second case was that of a man, aged forty-one, in whom Ménière's train of symptoms was followed by neuralgia and erysipelatoid inflammation of the face. It was impossible to say how much of the deafness was due to chronic middle-ear disease. There can be no doubt, however, that, after the attack of roaring in the ear, the hearing was rapidly destroyed.

The third case was that of a woman, aged fifty, in whom there was sudden, complete, and permanent destruction of hearing of one ear, following a tremendous roaring in the ear. Politzer's acoumeter was heard two inches from this ear when the other ear was open, but not at all when this was tightly closed. The watch was not heard when pressed against the auricle or the mastoid. Large tuning-forks of different pitch were not heard when held before the external meatus, but, when placed on the mastoid, were heard in the other ear. The hearing of the right ear was perfect. There was nothing abnormal in the external canal or the drum-membrane of either ear. There was no pharyngeal catarrh. The absence of marked vertigo was a noteworthy feature of this case, and would seem to make it probable that the disease was confined to the cochlea.

Caries of the Temporal Bone.—Sutphen (*Ibid.*) reports two fatal cases of this nature in which openings were made through the roof of the tympanum. The first case was that of a man, aged forty-four, who had suffered from otorrhœa for twelve years. The autopsy showed an immense abscess occupying nearly the whole of the anterior and middle lobes of the left hemisphere, containing a dirty-brown, fœtid pus. The opening made by the operation extended into the cranial cavity on the superior surface of the petrous bone, just in front of the superior petrosal sinus. In the depression just external to this a circle of dead bone appeared. To this the dura mater was attached, and perforated by a small circular ulcer. There was some localized meningitis. The instrument used at the operation had pierced the dura and entered the cavity of the abscess, but the flow of pus was prevented by the soft brain-substance or the dura itself acting as a valve.

The second case occurred in a man, aged twenty-one, who had had otorrhœa for ten years, with an acute attack of inflammation of two weeks' duration, which was evidently intra-cranial. The right external rectus was paralyzed, and there was choked disc in both eyes, with impaired vision. The patient lived ten days after being seen. On the day of his death an incision was made upward through the swollen tissue in the external auditory canal. A probe inserted through this cut passed over bare bone, slipped into a carious passage, and entered the cranial cavity. This bony sinus was enlarged with a trocar, but no pus escaped. The patient died comatose. At the autopsy the right lateral and superior longitudinal sinuses were found occupied by a large and partially organized clot; the walls of the sulcus were carious; circumscribed meningitis existed near the temporal bone, and there was softening on the surface of the middle lobe. The opening into the cranial cavity was found in the depressiou just external to the eminence for the superior semicircular canal, surrounded by carious boue. No accumulation of pus was found. The caries in the temporal bone involved the walls of the tympanum and the mastoid.

The Position of Reissner's Membrane in the Human Cochlea.—Steenbrügge (*Ibid.*) describes the results of his investigations upon Reissner's membrane in a very interesting paper. In a woman, aged thirty-four, who had died of tuberculosis, he found in the anterior lower wall of the left utricle, at the level of the lower margin of the fenestra ovalis, an elliptical perforation, measuring $1 \times 1\frac{1}{2}$ mm., which constituted a communication between the perilymphatic and endolymphatic spaces, which probably existed during life. In the cochlea of the same side, particularly in the second and third turns, there was a considerable deposit of hæmoglobin, with great dilatation of the vessels, which had ruptured at several places, causing extravasation of blood. There was also a peculiar condition of Reissner's membrane, which, owing to the draining off of the endolymph, sank down on the membrana tectoria and organ of Corti, in consequence of an excessive pathological stretching or relaxation. If the sinking down and apparent agglutination of this membrane had occurred during life, the function of the organ of Corti and of the membrana tectoria must have been impaired. If the elasticity of Reissner's membrane is acknowledged, the conclusion seems permissible that, in the human cochlea, a post-mortem relaxation of the vestibular membrane or loss of elasticity occurs in some instances, while in others it may be wanting or be present in a lesser degree. We thus see that the angle formed by Reissner's membrane in the pathological or histological specimen is in no definite relation to the curved shape it probably has in life.

The Terminal Cupule of the Ear.—Coyne and Ferré ("Ann. des mal. de l'oreille et du larynx") have been making some anatomical and physiological investigations upon the terminal cupule of the ear of some of the lower animals. The cupule is situated above the auditory crests and projects into the ampullæ of the semicircular canals. It appears like a brilliant, refracting corpuscle, of semi-hard consistence, at the posterior and superior part of the ampulla. Under the microscope it appears granular, refracting, and striated, presenting bands which are alternately bright and shaded. The number of terminal cupules found in a pyramid corresponds to the number of ampullæ. Their shape varies according to the shape of the auditory crests. The latter consist of several layers: 1. A layer of connective tissue traversed by vessels and nerves. 2. A special membrana propria. 3. A basement membrane. 4. An epithelial membrane formed of two layers. The auditory hairs play a double rôle of protection and of regulatiou of the ciliary vibrations through the medium of the terminal cupule. The entire apparatus seems to be one of accommodation for sonorous vibrations, and is also extremely well adapted for the perception of the irregular vibrations which constitute noise. The membrane of Corti is analogous to the cupule in its structure and relations, and it seems to act physiologically in the same way in regulating the vibrations of the cilia of the cells of Corti.

Traumatic Hæmorrhage into the Internal Ear.—Hardwicke (*Ibid.*) reports a case of this kind in a lad, aged seventeen, who was brought to the hospital at Sheffield completely deaf in one ear; the deafness had occurred four days previously from a blow on the side of the head with a cricket-ball. The watch could not be heard in the right ear, neither could the tuning-fork. Nothing abnormal was found in the pharyngeal mucous membrane or the middle ears. A diagnosis was made of hæmorrhage into the cochlea or semicircular canals. The treatment consisted in the application of leeches to the tragus, a blister behind the ear, and potassium iodide internally. The patient left the hospital cured on the eighth day.

Two Rare Cases of Mechanical Injury to the Organ of Hearing.—Moos ("Arch. of Otol.") reports a case of bilateral labyrinthine disease in a man, aged twenty-six, which was developed fifteen minutes after a stay of thirty hours in a diving apparatus. It manifested itself by nearly total deafness in both ears, tinnitus aurium, and vertigo, followed by staggering gait and inability to stand without support. It was caused by suddenly leaving the diving apparatus, after working in it, under a pressure of two atmospheres with but short intermission, for thirty hours. These symptoms were probably the result of a hæmorrhage in the labyrinth. The second case was in a man, aged thirty-four, in whom both drum-membranes were ruptured by the compression of air produced by the explosion of chlorophthallic ether during the making of eosine.

Loss of Hearing from Mumps.—Kipp (*Ibid.*) reports one case of this disease, in a young man aged eighteen, in which the total loss of hearing was in the right ear only, which was first noticed fifteen days after the commencement of an attack of mumps, while the patient was suffering from a metastatic inflammation of the left testicle. As all signs of irritation of the acoustic nerve were absent, it seems highly probable that the disease was limited to the cochlea. Whether the morbid process here was an inflammation with serous or hæmorrhagic effusion or embolism of the cochlear artery, it is difficult to say. Kipp thinks that an extension of the disease from the parotid gland to the ear along the facial nerve, or through the external canal and tympanic cavity, seems highly improbable; he thinks it much more likely that the inflammation of the parotid, the orchitis, and the ear affection are merely local expressions of the same morbid condition of the blood. Another case was similar to the first, except that there was no orchitis.

Chiseling of the Mastoid Process.—Hartmann (*Ibid.*) reports in detail the histories of fourteen cases in which it was necessary to open the mastoid process, and lays down rules for the performance of the

operation. The incision in the skin and the opening in the bone should be practiced at the line of attachment of the auricle, or at least immediately behind it. The possibility should always be borne in mind that in operating we may chance upon a sharp curve of the transverse sinus. The skin incision and the bony canal should be made so large that a free inspection of the wound cavity may be possible during the after-treatment. In order to keep the wound open, rubber tubes should be inserted immediately after the operation, to be replaced subsequently by thick and still later by thin lead ones.

Round-Cell Sarcoma of the Ear.—Green (*Ibid.*) reports an interesting case of this kind occurring in a man aged twenty-three. There had been a discharge from the left ear for seventeen years, following an attack of scarlatina. When the patient was first seen there was a muco-purulent discharge, and a spongy, very vascular, fleshy mass filled the left meatus, and seemed to be adherent to the wall. The left auricle was pushed outward and forward by a diffuse swelling over the mastoid, which had ruptured, and from the opening protruded a mass of fungous granulations two inches in length, dotted with spots of sloughing tissue, and bleeding freely on being touched. The meatus was filled with the above-described fleshy mass. Three days later the fungous granulations over the mastoid were removed, and the swelling was incised down to the bone, setting free a large amount of fluid and caseous pus. The bone was found extensively softened, and a large opening was made with a gouge in the mastoid antrum. The meatus was cleared from granulations, and carious communications were found to exist between the meatus and the mastoid. The case did well for a time, and then the bad symptoms reappeared, abscesses formed in the auricle and neck, and the growth returned and rapidly increased in size until it measured eight inches long, six wide, and four thick, and extended downward and in front of the auricle. Large masses sloughed away at times, giving rise to repeated hæmorrhages. The patient died from exhaustion about six months after the first operation.

Fracture of the External Auditory Canal by Contre-coup, with Rupture of the Drumhead.—Williams (*Ibid.*) reports an interesting case of this nature in a man, aged thirty-seven, who, while walking on a slippery sidewalk, lost his footing and fell backward, striking the back of his head against the ice with such force as to stun him. He remained for a time unconscious, vomited freely, and lost a large amount of blood from the ear. A splinter of bone from the auditory canal, not entirely detached, protruded through the skin. There was a stellate laceration of the membrana tympani. The piece of bone was removed with the forceps and measured 4 mm. by 3 mm. at its broader end, tapered to a point, and had a smooth periosteal surface on one side and a rough surface on the other. The patient eventually recovered, and the rupture in the drumhead healed. The fracture probably extended into the Glaserian fissure and terminated at the foramen lacerum medium. There was, no doubt, concussion of the entire labyrinthine contents, with a localized pachymeningitis.

Limited Caries of the Fundus as a Frequent Cause of Obstinate Otorrhœa.—Woakes ("Ann. d. mal. de l'oreille et du larynx") has a recent article upon this subject which may be summarized as follows: Certain cases of otorrhœa are very rebellious to treatment, and in these cases an examination will usually show the presence of granulations on the drumhead or in its immediate vicinity. This granulation tissue originates in the tympanic cavity, and by touching it with a probe there is felt a slight sensation of rugosity, the sign not only of simple hypertrophy, but of a carious process at some limited point of the bony wall. This explains the persistence of the otorrhœa. To combat this condition, Woakes employs a solution of sulphurous acid, with which he professes great success. The agent employed seems to dissolve the earthy salts in the particles of dead bone and to disinfect the diseased surface. It also acts as a stimulant to the process of cicatrization.

The Operative Treatment of Congenital Malformation of the Auricle.—Stetter ("Arch. f. Ohrenheilk.") reports in detail a case of deformity of the auricle as follows: The deformity consisted in the auricle being bent from above and behind downward and forward over the opening of the external canal, so that no sound-wave could enter the canal directly, which could only be looked into from below. The operation consisted first in dissecting up a triangular flap of skin, with the apex upward and the base on a level with the attachment of the auricle, and in dividing the subcutaneous cellular tissue by many small transverse incisions. It was then possible to lift up the apex of the auricle and to fasten it by sutures to the skin covering the squamous bone. To make this firm and lasting, two parallel incisions, 3 cm. long and 1 cm. from each other, were then made from the posterior surface of the auricle upward and backward toward the squamous bone. This flap of skin was then dissected carefully up with the subcutaneous connective tissue, and drawn forcibly upward, and by this duplicature of skin the new location of the auricle was made fixed and permanent. Both raw surfaces of this fold of skin, at the base and its further extension, were then united by sutures, and a firm bandage, with pressure on the helix, was applied. The result was satisfactory.

Diseases of the Ear in Typhoid Fever.—Bezold (*Ibid.*) recognizes three varieties of disease of the ear in the course of typhoid fever, viz.: 1. Hardness of hearing, without signs of inflammation and without any symptom in the drumhead or tympanic cavity, which seems to be due to some central changes. 2. Closure of the Eustachian tube with consecutive sinking of the drumhead. 3. Purulent inflammation of the drum-cavity, either without perforation or with perforation of the drum-membrane, and otorrhœa. The so-called nervous deafness is characterized exclusively by subjective symptoms, varying and moderate deafness, and tinnitus. As regards the affection of the Eustachian tube, he does not think that it occurs more frequently in typhoid-fever patients than in healthy persons. Both these varieties of disease are met with in the beginning of the fever, but the inflammatory disease of the middle ear occurs toward the end of the abdominal affection. The results of the autopsies were as follows: 1. A glairy mucus in the Eustachian tube was found in six cases. 2. Secretion in the drum in four cases. 3. Simple hyperæmia of the mucous lining of the drum in two cases. 4. Succulent swelling of this mucous lining in three cases. 5. Succulent swelling and extravasation of blood in a circumscribed spot of the mastoid cells in one case. 6. Extravasation of blood in the drumhead in two cases. 7. Perforation of the drumhead in two cases. 8. Nothing abnormal in two cases. Bezold considers that the purulent otitis media met with in typhoid fever may arise in three ways: 1. The direct propagation of the inflammation of the naso-pharynx through the Eustachian tube. 2. The introduction of septic material from the naso-pharynx directly into the middle ear. 3. Emboli of the vessels of the mucous membrane of the middle ear, from endocarditis and thrombus of the left side of the heart, or from purulent deposits at the periphery.

Clonic Spasm of the Levator Palati which produced a Rhythmic Ticking Noise.—Williams ("Zeitsch. f. Ohrenheilk.") reports a rare case of this kind in a well-developed girl of twelve years of age, in whom the affection was in all probability connected with chorea. The noise was probably produced by the vacuum which was caused at the moment when the upper surface of the velum separated from the roof of the naso-pharynx, with which it was brought in contact by spasmodic contraction. Williams had an opportunity to watch the velum during an attack of acute amygdalitis, and found that the ticking noise was absent, although the spasm of the levator was still present.

Miscellany.

The International Medical Congress.—The "Medical News" publishes the following letter from Sir James Paget, dated London, July 22, 1885:

"Dear Dr. Hays: I am very sorry to learn from some of your journals, as well as from letters which I have received, that there are serious differences of opinion among the members of our profession in your country as to the arrangements to be made for the International Medical Congress which it is proposed to hold in Washington in 1887. The deep interest which I feel in the Congress makes me venture to write to you in the hope of helping toward a right decision of some of the questions in dispute, and chiefly by stating what I believe to have been the custom at former meetings.

"I believe that a principal question relates to the authority, if any,

which was given by the Congress at Copenhagen in 1884 to the gentlemen who conveyed the invitation that the next meeting should be held in the United States of America.

"I believe that it has never been considered that the members at one Congress should give any formal authority for any part of the organization of the next. At each meeting some place has been named at which it was deemed desirable that the next should be held; and at the same time, or soon afterward, some persons of high repute in that place have been asked to take such steps as they might deem necessary or most likely to promote a successful meeting.

"Thus, after the Congress at Amsterdam in 1879, the president, Prof. Donders, wrote, in the first instance to Sir Joseph Lister and Sir William Bowman, and by them, and those whom they asked to act with them, the first and all the principal subsequent measures were adopted for the promotion of the meeting in London. Sir Risdon Bennett, the chairman of the Executive Committee, communicated to Prof. Hannover and Prof. Panum, of Copenhagen, the desire that the next meeting might be in one of the chief cities of Scandinavia; and those gentlemen, and others acting with them, began and had the principal part in all the arrangements for the Congress in Copenhagen.

"I fully believe that it was understood at Copenhagen that the same course would be pursued in the organization of the Congress to be held at Washington. I was at the general meeting at which, after some discussion, the majority of the members present expressed the wish that the next Congress should be in the United States; and I have no doubt that it was expected that the distingnished American gentlemen there present would obtain the co-operation of the most eminent of their professional brethren, and would, with them, make all the arrangements which they should deem best.

"Certainly it was not supposed that the Congress would be regulated, with any degree of exclusiveness, by the members of one medical association, however numerous; and I think it quite as certain that, if this had been thought possible, the proposal that the next meeting should be held in the United States would not have been adopted.

"I am sorry, also, to feel sure that if the Congress be not supported by the eminent men who have now declared that they will take no part in it, the members of the profession in this country who will attend it will be very few. And in this opinion, as well as in all that I have written here, I have the concurrence of several of the most influential of the London Congress with whom, before this writing, I consulted."

Editorially, the "News" says:

"We invite careful attention to a letter appearing in another column, which has been received from Sir James Paget, who, as the immediate predecessor of the lamented Panum in the presidency of the Congress, and as a member of the existing Executive Committee, speaks in reference to the organization of the next Congress with the highest authority. This letter commends itself to the thoughtful consideration of every physician who has the true interest of the American profession at heart, and it will give light to some who desired more authoritative information than they have yet possessed to guide correctly their future course of action.

"It has been asserted by the editors of one or two medical journals that the Executive Committee of the last International Medical Congress no longer exists, that therefore the Congress must meet next in this country, and hence that the American Medical Association plan must be adopted and supported. We have now information from members of the Executive Committee of the Copenhagen Congress that that committee is considered to be still in existence, that it still has work to do, and that it will by no means hesitate to assume the responsibility of ordering that the Congress shall meet in Europe instead of this country in 1887, in case it considers that such change of place of meeting would be for the interests of the Congress. And, if it does issue such a notice, there can be no doubt that it will be obeyed.

"Of this committee Sir James Paget is one of the most prominent and influential members, and hence his opinion demands the most serious consideration. This opinion is clear and straightforward. '*Certainly it was not expected that the Congress would be regulated with any degree of exclusiveness by the members of one medical association, however numerous, and I think it quite as certain that, if this had been thought possible, the proposal that the next meeting should be held in the United States would not have been adopted.* I am sorry, also, to feel sure that, if the Congress be not supported by the eminent men who have now declared that they will take no part in it, the members of the profession in this country who will attend it will be very few.'

"We consider it as now certain that the European members of the Congress have, through their Executive Committee, the power to prevent any material interference with the organization and work of the Congress itself, but, while this does away with our fears lest the progress and usefulness of these great international scientific gatherings should be checked by the action in this country, it increases our anxiety as to the effect of this discord upon our reputation abroad, and on our associations at home.

"The action of the original committee—of the American Medical Association—and of the new committee, is now generally understood; and there does not seem to be much use in further comment and criticism upon what is past. The important question now is as to the future. Is there any way by which the impending disgrace can be averted? If there is, it must be such as will induce those who have withdrawn from the organization to return and co-operate heartily. To the best of our knowledge and belief, derived from an extensive correspondence and from personal interviews, there is but one way to do this, viz., by dropping the code question entirely, confirming all the appointments of the original committee, and leaving to the enlarged committee which it created, including the presidents of the sections, the work of making additional appointments, completing the organization, and carrying out the work to its completion. If this be done, we believe that questions of appointments, etc., will be settled to general satisfaction, and that, although the difficulties of the work will be greatly increased, the Congress will be, what we all desire it should be, a great success.

"If this be not done, we do not believe that the Congress will meet in this country in 1887."

The "Boston Medical and Surgical Journal" says:

"It has been evident for some time that the prospect for a successful international congress in this country was very small. It is impossible to expect men of scientific attainments to cross the water to take part in a congress about which there is so much misunderstanding as in the present instance. It is exceedingly unpleasant to accept hospitalities in a house whose inmates are unable to agree as to the manner in which such hospitality shall be shown.

"We are permitted to-day to print a letter from a medical gentleman, well known on this side of the water, which expresses the attitude which men, interested in the science and not at all in the politics of medicine, must necessarily take. The letter is addressed to Dr. J. Collins Warren, and is as follows:

"'London, 13 Harley Street, *July 25, 1885.*

"'My Dear Collins Warren: I have seen in medical papers, and heard through private sources, that a serious disagreement has occurred in respect to the organization of the ensuing International Congress in Washington. A few of those who had been concerned in organizing the London Congress recently met to talk the matter over, for we feel that any failure which might attend the Congress in the United States would be little short of a professional disaster. I do not myself think, and most here would share my opinion, that a congress from whose ranks some of your best physicians and surgeons have determined to withdraw, and whose members are to be further restricted to such as belong, either directly or by affiliation, to one medical body in America, would be likely to be attended by many colleagues from this country.

"'Speaking from personal knowledge, an international congress can not be a success unless taken up in the warmest and most self-sacrificing manner by all the principal men in the country where it is to be held. I was present at the meeting in Copenhagen, where the invitation to meet in America in 1887 was given, and after some discussion accepted. I am sure it was present to the mind of every one there that the invitation was one from the profession of America, and not from any section of it, or any particular medical society in it. Otherwise, I I feel pretty certain Prof. Virchow's invitation to meet on the next occasion in Berlin would have been accepted.

"'Even now it would appear to me wiser to have that invitation renewed, or to meet in some other place, than to have a meeting in America, from which, so far as we may at present judge, many of the chief men on both sides of the Atlantic would absent themselves. You are at liberty to use this letter as you deem fit.

"'Yours very faithfully,

"'William MacCormack.'

"It is not easy to see how the matter can be remedied so as to counteract the disagreeable impression already made upon foreigners. What the committee may be able to accomplish at its extra meeting in September can only be conjectured, but we are very skeptical as to their power to accomplish any good results. Certainly nothing can be expected from men who consider the numerous resignations that have taken place as manifestations of a conspiracy, or as part of a game of bluff. We trust the editor of the 'Journal of the American Medical Association' will be able to comprehend, at least, that the opinion represented by the above letter is not the expression of those who have 'deliberately undertaken to obstruct the work of organization.'"

The "Progrès médical" says: "We learn by the 'Medical Times' that the organization of the International Medical Congress at Washington is meeting with certain difficulties among our *confrères* beyond the sea. The American Medical Association disapproves of the acts of the committee named at Copenhagen, although the latter had joined to itself a great number of members of the association. It preferred to replace the committee by another made up wholly of its own members. It would be ungracious in us to criticise the honorable medical association of the United States in any way, but it is incontestable that this way of acting is contrary to the usage followed by the International Medical Congress thus far, and, as the 'Medical Times' very justly says, it involves great risk of compromising the success of these international reunions for ever. What is none the less certain and none the less grave is, that thus many of the American members who are held in the highest esteem here, and enjoy the deepest sympathy, would be alienated from the Congress. However attractive it would be for us to extend the circle of our acquaintance and to contract new relations, we should be quite as well pleased to see again those whose names have long been known to us, and whom we are proud to call our friends. There is no doubt that any indignity put upon them will considerably chill the zeal of their Old-World colleagues in trusting themselves to the uncertain waves of the ocean."

The "Journal of the American Medical Association" says:

"Evidences are not wanting that the principal performers in the grand comic play of 'Much Ado about Nothing,' which was commenced so brilliantly on the 29th of June by twenty-eight prominent members of the profession in Philadelphia, are becoming weary of their work. Some who were induced to join in the play from the first impulse have already withdrawn, and others are evidently preparing to follow.

"Dr. John H. Packard, of Philadelphia, who was appointed secretary-general of the Congress by the Committee of Arrangements at the meeting in Chicago, and whose name was published as one of the twenty-eight who declined to accept any place in the revised organization, has recently withdrawn his declination and accepted the position. As an offset to the other twenty-seven who started the scheme of obstruction and factious opposition in that city, we have the names of seventy prominent members of the profession in the same city who have freely indorsed the action of the American Medical Association, and pledged their support to the organization of the International Medical Congress of 1887. Among them are the names of teachers and authors as eminent and as well known, both in this country and in Europe, as any of those who so hastily declined. To the same indorsement and pledge are appended the names of several hundred prominent and well-known members of the profession in other parts of the State of Pennsylvania.

"For further evidence of public sentiment in the same direction, the reader is referred to the resolutions in the present number of the journal, passed by a joint meeting of the Northeastern and Northwestern Ohio Medical Societies, which embrace the profession in about forty counties of that State.

"The idea that the Committee of Arrangements will not be able to complete the work of preliminary organization at its coming meeting on September 3d, or that the vacancies in the several sections can not be filled with men of the highest standing and ability, is simply absurd. And, if the changes are made in the rules that were indicated in the journal of August 8th, there will not be left the vestige of a foundation on which opposition can rest, except that afforded by personal prejudice alone."

The British Medical Association and the American Medical Association compared.—"A statement was made in a recent issue of this journal," says the "Maryland Medical Journal," "that the profession in the United States greatly needed a national scientific association that was capable of meeting all the requirements of a vigorous and intelligent scientific organization.

"For some years past the American Medical Association has attempted to represent the interest of scientific medicine in this country. Quite recently the profession has been made aware of the fact that the American Medical Association is totally incapable of dealing with serious and important medical interests. Whatever value it may have to the medical profession, it is a serious fact that interests of the profession are not subserved by the association in a manner to give entire satisfaction. There are serious defects somewhere in its organization and conduct, and, unless these are plucked out, the association will remain a crippled and feeble scientific organization. The faults which exist in the plan and government of the association must, in our judgment, be corrected before it can take a healthy, vigorous, and intelligent grasp upon the profession, and before it can rise to the highest aims and purposes of a national medical organization. It is not our purpose to suggest remedies for the ill-health of the association, but we propose to show by way of comparison that the association is in an unhealthy physical and mental condition. We will permit some of our exchanges to make a diagnosis of the pathological condition which is undermining the vitality of the association and to suggest the appropriate treatment.

"We have before us the Annual Report of the Council of the British Medical Association, which was presented to this body at its fifty-third annual meeting, held July 28th, 29th, 30th, and 31st. From this report we are able to present a number of useful and suggestive facts relative to the highly prosperous and progressive condition of the British Medical Association, a scientific body which bears pretty much the same relations, ostensibly, to the profession in Great Britain that the American Medical Association claims to do to the profession of the United States.

"This report says that on July 1, 1884, the membership of this association numbered 10,826; of these, 123 have since died, and 162 have resigned; 708 members have been elected during the year, leaving a total of 11,249 members on the roll of the association on June 16, 1885. This report also states that the revenue of the association for the year ending December 31, 1884, was £22,256 and the surplus after paying expenses was £2,319. The total invested funds of the association, exclusive of trust funds, amounted to £19,541. The association owns and publishes the "British Medical Journal," a publication which enjoys not only a high reputation at home, but throughout the world. Apart from the valuable work the association journal is doing for the profession in Great Britain, the association expends a large sum of money each year in promoting original research and in advancing scientific medicine.

"The association has organized various branches in different sections of Great Britain, which add largely to its efficiency and prosperity. The various committees appointed by the association have charge of all questions which affect public and professional interests. It is safe to say that no medical organization is doing more to elevate the standard of scientific medicine and to promote the best interests of the medical profession than the one under consideration.

"As we see the machinery of the British Medical Association in operation and observe its movement, we are reminded of the power and effectiveness of thorough organization, and its vast possibilities when guided by intelligence and sound judgment.

"The British Medical Association owes its prosperity to the fact that its whole organization is based upon an active and intelligent principle. It exists for the entire profession in Great Britain, and its con-

duct is regulated by the highest aims and needs of the profession. Men who seek honors at its hands do so in obedience to high principles and motives. The association does not exist to give prominence to men who can only reach prominence through its agency. It is not a political or sectional body that flips about over the country at the bid of a few hospitable members. Its aim and purpose is strictly scientific. Its members take a pride in promoting its best interests from the fact that the association is promoting the very highest professional interests.

"Let us consider, by way of contrast, the American Medical Association.

"This association has been in existence since the year 1847. It has an average membership of less than three thousand. It owns little or no property. It has done but little to promote original research, and it has not been able to grasp hold of the various questions which interest the American profession. The association has a code of ethics, which has probably (?) done more for the profession than anything else, but, apart from this feature of regulating ethical questions, it has nothing to proclaim to the world as worthy of high respect or consideration. The annual meetings of the association may possibly do good in a social and semi-scientific way. These gatherings at times have been enjoyable reunions, and we believe tend to promote good feeling, to create friendship, and to elevate the professional tone. But we ask, Is there not a serious and important work for a national medical association to do? Are there not scientific and professional interests in the United States which can only be promoted by a national association? The medical profession in the United States now numbers between sixty and seventy thousand members—about double that of Great Britain, we believe. Many of these men are practicing medicine in the most ignorant and unscientific manner. The public and the profession is being ignominiously wronged by the herds of quacks that flood our land. With no organized power to deal with the important relations of scientific medicine to society, the medical interests of this country are annually going from bad to worse. We repeat, Shall we have a vigorous, intelligent national medical association, or shall we continue to follow the fortunes of the one which is ill from its own incapacity and sluggishness and which has, of late years, manifested little strength beyond that for log-rolling and wire-pulling for its high honors? Shall the American Medical Association be reorganized and thus be lifted out of the rut of degeneracy into which it has fallen, or will the scientific minds in the profession establish a national association capable of meeting the requirements of an enlightened and scientific body of medical practitioners? These are serious questions for professional consideration at this time. Who will answer them?"

Good Health results from Sanitary Work.—Under this heading, the secretary of the Michigan State Board of Health, Dr. Henry B. Baker, of Lansing, says:

"Sanitary authorities have maintained that the sanitary work which they have recommended to be done as a preparation for cholera—such as preventing and abating nuisances; attending to drains, sewers, privies, and cesspools; cleaning up generally, and unusual carefulness in regard to foods and drinks—would reduce the sickness and deaths from other diseases, even if cholera did not come. The weekly reports for July, 1885, to the Michigan State Board of Health, by physicians in different parts of the State, indicate that this is being realized in Michigan so far as relates to the lessened sickness—it having been lessened from nearly every disease, and greatly lessened from fevers and from diarrhœal and other diseases, believed to be especially influenced by sanitary conditions; and this is true notwithstanding the meteorological conditions in that month were rather more than usually unfavorable to health. It is proper to state, however, that the sickness in any month is influenced by the meteorological conditions in the preceding month, and that the meteorological conditions in June, 1885, were favorable to health.

"Observations in Michigan for many years have shown that in July the meteorological conditions especially unfavorable to health are, high temperature, excessive humidity of the atmosphere, and deficiency of ozone. The bulletin of health in Michigan, July, 1885, says: 'For the month of July, 1885, compared with the average of corresponding months for the seven years 1879–'85, the temperature was slightly higher, the absolute and the relative humidity were more, and the day and the night ozone were less.'

"'Compared with the average for the months of July in the seven years 1879–'85, remittent fever, intermittent fever, dysentery, consumption of lungs, cholera infantum, diarrhœa, cholera morbus, measles, and whooping-cough were less prevalent in July, 1885.'

"A large part of this decrease in sickness has undoubtedly been due to the medical and sanitary journals and the newspapers, which have constantly kept before the people the necessity for sanitary work and the facts as to the spread of cholera in Europe.

"It remains to be seen to what extent efforts for the exclusion of cholera from this country, and the general preparation for cholera by boards of health and the people, shall prove effectual; but, even if cholera shall not be entirely prevented, there will remain the belief that the measures which have so greatly decreased the sickness from other diseases can not but have had their influence in decreasing it; and, if cholera does not occur in this country, it seems quite probable that, by reason of the suffering elsewhere, there may be as many cases of serious sickness prevented in this country as there have been cases of cholera in Europe. But this may not continue without continued vigilance and effort."

Dr. Baker supports his remarks with the following tabular statement:

Health in Michigan in July, 1885, compared with the average in July for the seven years 1879–'85:

Diseases arranged in order of greatest diminution of sickness in July, 1385.	PER CENT. OF REPORTS, STATING PRESENCE OF DISEASE.		Per cent. of reports more (+) or less (−) in July, 1885, than the average for July, 1879–'85.
	In July, 1885.	Average in July, 1879–'85.	
Remittent Fever	30	51	− 21
Dysentery	15	32	− 17
Intermittent Fever	65	82	− 17
Consumption of Lungs	48	63	− 15
Cholera Infantum	20	33	− 13
Diarrhœa	62	74	− 12
Cholera Morbus	39	49	− 10
Measles	8	17	− 9
Whooping-cough	14	22	− 8
Pneumonia	10	16	− 6
Typho-malarial Fever	10	15	− 5
Diphtheria	11	16	− 5
Bronchitis	41	46	− 5
Rheumatism	59	64	− 5
Inflammation of the Kidney	17	21	− 4
Scarlet Fever	11	14	− 3
Typhoid Fever	6	8	− 2
Membranous Croup	1	2	− 1
Small-pox	0	1	− 1
Inflammation of the Bowels	16	17	− 1
Influenza	18	19	− 1
Erysipelas	21	22	− 1
Neuralgia	58	59	− 1
Puerperal Fever	6	6	=
Inflammation of the Brain	6	6	=
Cerebro-spinal Meningitis	8	5	+ 3
Tonsillitis	36	32	+ 4

"It will be seen that there was less sickness than the average for July from nearly every disease reported. From only two, cerebro-spinal meningitis and tonsillitis, was there an increase."

Elastic Electrodes.—It is often convenient to use large surface electrodes, and it is desirable that they be so made as to adapt themselves readily to inequalities of the surface. Zinc, lead, and various other materials have been used for the purpose, and have been found to answer tolerably well, but they are simply flexible, and not elastic; consequently they do not recover their flat shape after being used, and some of them are open to the objection that they are uncomfortable for the patient to lie upon, while in others the metallic portion is quite small in comparison with the extent of sponge attached to them, so that the current is not so diffused as is sometimes desirable. To remedy these defects, Dr. James Craig, of Jersey City, has hit upon the expedient of using electrodes made of woven brass wire nickel-plated.

Dr. Craig has shown us a set of these electrodes, and it is certainly to be said of them that they seem admirably calculated to do away with the objections we have mentioned.

Cholera in India.—Under date of July 6th, the Bombay correspondent of the London "Medical Times and Gazette" says: "I have again to notice a considerable increase of cholera in Quettah and the adjoining districts. The cantonments have had to be evacuated, and the troops placed in tents at a distance from the place. The works on the railway under construction have had to be suspended until the abatement of the disease. The cholera is now raging virulently at Kurrachi. It is all very well for the promulgators of the non-contagion theory to stick blindly to a view which can never hold for a moment where both sides of the question are duly represented. In the case of the Quettah epidemic there is little room for doubt that the cholera was carried *by human intercourse* from Bombay, which now may take rank as an 'endemic area.'"

The New York Post-Graduate Medical School and Hospital.—In the "Announcement," recently issued, we find the following gratifying statement: "The fourth year of instruction begins on September 12, 1885. The faculty have found their new building very well adapted to the purposes of a school for advanced medical instruction, a dispensary, and hospital. This large structure is situated in one of the healthiest locations in the city, very near to Gramercy Park, and accessible to the large hospitals. Since the last announcement, the wards and rooms of the hospital have been constantly occupied by patients, whose cases have been made available for instruction, while the dispensary has furnished ample material in ambulant patients. There are histological and pathological laboratories connected with the school, as well as one for physiological investigations. During the year a large sum of money has been given the hospital by a benevolent lady, through one of the lecturers of the school, for the purpose of fitting up and supporting a ward for the treatment of sick children. It is believed that similar gifts will enable the faculty at no distant day to fully support from endowment funds a large number of beds, so that a hospital sufficient for all purposes of instruction, except in general surgery and medicine, may be found within the walls of the school."

The Various Pharmacopœias.—On the authority of Kobert, "Lyon médical" gives the following statement as to the number of drugs recognized in the various pharmacopœias:

French	2,000
Spanish and Belgian [? each]	1,500
Russian	1,080
Greek and Swiss [? each]	1,040
United States	1,010
British	815
Swedish	740
Danish	720
Dutch	665
German	600
Austrian	560
Hungarian and Roumanian [? each]	545
Norwegian	530

The Failure of the Vivisection Bill in Pennsylvania.—The "Medical and Surgical Reporter," of Philadelphia, says:

"The Pennsylvania branch of the American Society for the Restriction of Vivisection has lately distributed several tracts and pamphlets in pursuit of its aims, and to influence the public in favor of its efforts. One of these is entitled 'Facts in regard to the failure of the bills presented to the Legislature for the restriction of vivisection.' The brunt of this statement bears heavily on Drs. H. C. Wood and S. W. Mitchell. They are accused of having promised the society to support a bill which, before the legislative committee, they threw cold water upon.

"A careful reading of the 'statement of facts'—and we have not sought other sources of information—will easily explain the position assumed by these gentlemen. Both of them, and for that matter all physicians, are perfectly willing to support a bill restricting vivisection, provided that, a sensible restriction being admitted, the matter will end there, and no further agitation be begun to do away with it altogether. This was the assurance Dr. Mitchell asked, and that the society did not give. They say their committee was not prepared for the question. We ask, Are they prepared now to give an affirmative reply? We have good reason to know they are not. We have excellent authority for saying that the society intends to continue to agitate and appeal, with the hope of abolishing vivisection entirely. This is evident from their pamphlets, as well as their spoken utterances. Their name, 'For restricting vivisection,' is merely a disguise for their real intentions, and not an honest intimation of their final purpose.

"Such being the case, all must approve of the action of the gentlemen named. They did not intend to commit themselves to the projects of a society which declined to express its real designs, and merely wanted to use them as stepping-stones to results which they condemned.

"While disapproving of causing unnecessary pain to any organic creature, we acknowledge but little sympathy with the sentimental affection for brutes now so prevalent. To a well-ordered mind, no sight is less pleasing than to see a woman fondling and kissing some ugly cur of high degree, when her own children are lacking in physical or moral education, or when she is taking nightly precautions not to have children—and this sight is no rare one in our civilization."

THERAPEUTICAL NOTES.

Sulphide of Carbon.—In a recent number of the "Progrès médical" we find a *résumé* of a graduating thesis on this substance, by M. Sapelier. The writer insists on the importance of distinguishing between the commercial article and pure sulphide of carbon, the former being contaminated with sulphide of hydrogen in varying proportions, to the action of which the poisoning of workmen engaged in the manufacture is attributable. Sulphide of carbon is available in medicine as a rapid and energetic revulsive, and, in solution, it is one of the best of intestinal antiseptics, especially in typhoid fever. The same journal gives the substance of a recent communication on the same subject, made before the *Académie de médecine*, by M. Dujardin-Beaumetz, who gives the following formula for a solution for internal use (*eau sulfocarbonée*):

Sulphide of carbon	375 grains;
Essence of mint	50 drops;
Water	16 ounces.

This is to be shaken and allowed to settle. From four to ten dessertspoonfuls of the solution may be given daily.

Nitro-glycerin in the Treatment of Interstitial Nephritis.—As opposed to the theory that a sufficient urinary excretion is kept up by the increased arterial pressure consequent upon the cardiac hypertrophy, Rossbach ("Berl. klin. Woch."; "Union méd.") adduces the results which he produced with nitro-glycerin in three cases of contracted kidney, in which the patients had increased arterial tension, albuminurie retinitis, uræmic asthma, and the general ill-health characteristic of generalized and advanced arterial sclerosis. In spite of the lowered tension produced by the drug, the uræmic symptoms were diminished, the urine was increased in amount, the albuminuria became less evident, and the retinitis grew less marked and less troublesome.

An Ointment for Intertrigo.—In a recent discussion at the Paris *Société de thérapeutique*, M. Campardon ("Progr. méd.") stated that an ointment made after the following formula had answered well in his experience:

Borax	30 grain;
Oil of wintergreen	10 drops;
Vaseline	7½ drachms.

A Calmative for Teething Children.—M. Vigier ("Gaz. hebdom. de méd. et de chir.") gives the following formula of a *sirop de dentition:*

Hydrochlorate of cocaine	1½ grain:
Tincture of saffron	10 drops;
Syrup	2½ drachms.

The painful gums are to be gently rubbed with this syrup several times a day.

Original Communications.

RHACHITIS.*

BY HENRY N. READ, M. D.,
BROOKLYN.

RHACHITIS, though a very common and important disease of childhood, has received, in this country at least, much less attention than it merits. Since I have been a member of this society I can not recall a discussion of or paper upon this disease. Occasionally, in the pathological societies of this city or New York specimens of this disease are exhibited, but they are usually confined to the grosser and later lesions of the disease. My object is, in this communication, to call attention to the earlier manifestations of rhachitis—those manifestations which are not infrequently overlooked in the treatment of cases, but which, unless recognized and treated, will often render nugatory all remedial measures adopted. One can not but be struck at the large number of fatal cases of the simple catarrhal diseases when looking over the mortuary reports of these two cities. In the cold months bronchitis and the warm months diarrhœa appear with great frequency as the causes of death in the statistics. These disorders, if simple and occurring in healthy children, do not excite alarm, and are very manageable. The mortality from them, therefore, means something more than appears on the faces of the death certificates; and, on examination, rhachitis will be often found as the silent factor in the production of the fatal result. A somewhat extended experience in the department of pædiatrics, both as a practitioner and as physician to public institutions in this city, has established the opinion in my mind that rhachitis is second only to tuberculosis, and indeed not very far second to this disease as a general or constitutional disorder of childhood—far more so, I believe, than either struma, syphilis, or simple atrophy. Rhachitis is never a congenital disorder, nor, strictly speaking, even a diathetic disease, if by diathesis we mean a *constitutional predisposition* to the development of a certain affection. It is rather a developmental disorder brought about by exterior surroundings, though, of course, it may be developed in those children who have an inherited tendency to other diseases. Its great frequency, its vicious modification of unimportant maladies, and its injurious tendency if not recognized and treated, render this affection, therefore, of peculiar interest to the practitioner. Rhachitis may be defined, then, as "a general disease," not hereditary or diathetic, "affecting the nutrition of the whole body; arresting natural growth and development; perverting and delaying ossification; retarding dentition; causing the bones to become soft and to yield to pressure, and the muscles and ligaments to waste; and in many cases producing alteration of the brain, liver, spleen, and lymphatic glands." To treat exhaustively of the ætiology and pathology of rhachitis would require an article of greater length than can be condensed into the limits of one of several papers of an evening, and I shall therefore briefly outline this portion of my subject, as I wish to speak principally of the earlier clinical symptoms of the disease—a recognition of which is of great importance. Rhachitis is produced by one, or the conjunction of several agencies. It is a direct consequence of malnutrition, and its causes must therefore be sought for in all the numerous agencies which injure the nutrition of the developing child. The prime ones are those which fall under the heads of improper food and defective hygiene. Insufficient and especially *unsuitable* food, and want of fresh air and *sunlight*, are the two causes to which rickets may be charged. The first two, by starving the body, and the last two, by rendering assimilation defective, produce, either together or alone, that condition which we know as the rhachitic condition. The majority of cases are found, of course, among the poor, but the disease is by no means confined to this class. A very considerable number of cases occur in the ranks of those denominated "independent," and not infrequently does it occur among the very wealthy and luxurious. Among the poor, if I should designate any *one cause* which I consider more potent than another in the production of rickets, I should undoubtedly indicate *want of sunlight*. Among the rich, or those in comfortable circumstances, *improper food* takes the first place. When the nursing child is weaned is the time usually for the commencement of rhachitis. The mother's milk is replaced by the starchy foods in such kind or quantity as to impair assimilation, and the morbid process is set up. Rhachitis may also be developed by too long a continuance of nursing, the mother's milk being, from age or impoverishment, unsuitable to the growing wants of the system. Rhachitic children from this cause may often be noticed where mothers who have borne children rapidly continue to nurse the youngest for a long time after the proper age for weaning has arrived, to prevent a new pregnancy. The location of the habitation, I have frequently noticed, produces a marked effect on the development of rhachitis. The basements of tenement-houses and the rooms on the northern side of a house will produce more rhachitic children, other things being equal, than rooms more favorably situated. The age at which rhachitis is produced must be noticed. It is seldom seen under one year of age, and almost never under six months. The cases of so-called "congenital rhachitis" are not true cases of the disease. Neither is there any connection between rhachitis and congenital syphilis, though Parrot has labored with no little ingenuity to show them to be identical. The period of its inception, therefore, shows a close connection with weaning, and naturally with the ingestion of unsuitable food. The tubercular diathesis, strange to say, seems to wield a protective influence against rhachitis. This is probably explained by the fact that children who are born tuberculous will, from the causes which develop rhachitis—viz., bad air and food—die of tubercular phthisis ere rhachitis can be set up. The pathology of rhachitis must be passed over briefly. The first and chief pathological change in this disease is the generation of lactic acid in the deranged digestive organs of children. Heitzman as-

* Read before the Medical Society of the County of Kings, June 16, 1885.

serts that this acid excites irritation in the osteoplastic tissue, and at the same time dissolves and helps to eliminate the calcareous tissue already formed. If, in addition, the food given the child be deficient in the lime salts, the rhachitic process, it is obvious, is hastened and made sure. The brunt of the disease falls upon the bony structures, though nearly all the tissues of the body are more or less affected, and some of them early in the disease. The bones are exceptionally rich in water, fat, and carbonic acid, but deficient in the lime salts—the normal proportions of these ingredients being reversed from 63 to 65 per cent. to 37 to 35 respectively, inverted, as it were, from the healthy standard. The bones become then of less specific gravity, and are softer and more easily bent or broken. The epiphyseal ends of bones are always enlarged, and the periosteum thickened, inflamed, very vascular, and with difficulty detached from the bony structure underneath. The microscopical changes in the osseous tissues consist, according to Kölliker, Virchow, and Müller, of a remarkable extension of the spongy layer, an abundant proliferation of the cartilage cells in the primary cartilage layer, in deficiency or complete absence of calcification of the osseous and cartilaginous substance, in disproportionate extension of the medullary cavity, and delayed alteration of the cartilage tissue. The formation of bone out of the cartilaginous tissue takes place irregularly, and the *zone of proliferation*, as the vertical columns of the corpuscular elements which are forming to receive the deposit of earthy salts are called, is not separated from the *zone of calcification*—the layer which has already received the deposit—by a well-marked line of demarkation as in healthy bone. The two zones are greatly thickened and ossification takes place irregularly, little spiculæ and islets of bone being found in the proliferating layer, and incomplete ossification in the calcified layer. According to a late observer, Strelzoff, the osseous trabeculæ, from this irregularity of formation, have an abnormal arrangement, and are disposed *radially* instead of *concentrically*. This arrangement is supposed to be an additional cause of weakness, therefore, in the bone, and to render it still less capable of resisting pressure or strain. The muscles in this disease are small, flabby, soft, and pale, the striæ being very indistinct. The brain is small and shrunken, and fluid is usually exuded to fill up the cavity of the skull, which is generally enlarged. For the reasons before mentioned, the pathology of the internal organs must be omitted, as well as those very interesting morbid changes which take place in rhachitis from mere mechanical causes, such as pulmonary collapse and emphysema, hepatic engorgement and fatty degeneration, etc. To speak briefly of the *prognosis* in rhachitis, before passing on to the symptoms, it may be stated to be good, provided the disease is recognized early. In none of the constitutional diseases, except the congenital syphilis of infants, do we get better results from proper treatment than in rickets; but to be managed successfully it must be recognized in the early stages. It is rarely a primary cause of death, but as a secondary cause it is second to few of the diathetic diseases. Vast numbers of deaths from bronchitis—simple and capillary—pulmonary collapse, diarrhœa, laryngismus stridulus and other disorders, are really due to rhachitis. The symptoms of rickets can be readily recognized, but are often in my experience overlooked or misinterpreted. The first symptoms are the sweating about the head, the feverishness at night, the tendency to kick off the covers on the part of the child, the indigestion, grinding of the teeth, diarrhœa alternating with constipation, pasty, dull complexion, circles under the eyes, and tumid belly. These cases are nearly always treated for worms before the real trouble is suspected. Next in order the child becomes fretful and cross, and cries if moved or dandled, evidently suffering pain from handling. He sits quiet and makes no attempt to move; will play with toys put into his hand, but makes no effort to go after them. The digestive derangements at first are limited to a lessening of the digestive powers; indeed, the symptoms pathognomonic of rickets are always preceded by those general symptoms which indicate simply impaired nutrition. Such have been mentioned. The stools are large, pasty in consistence, offensive in odor, and contain large quantities of undigested materials, as well as slime and greenish masses. Flatulence is common. The urine is very acid and causes pain in voiding. The sweating, slight at first, now becomes very profuse, and occurs principally during sleep. Beads of moisture stand on the brow of the child, and the pillow is usually wet in the morning. Following this commence the changes in the bones characteristic of the disease. The ends of the bones are enlarged and the shafts thickened. All the joints are notably increased in size, the wrists and ankles being peculiarly noticeable. Great tenderness is manifested not only in the bones and joints, but in the muscles also. The bones of the upper extremities are affected first, and first of these usually are the ribs. The enlargement of the sternal ends of the ribs is one of the most commonly recognized symptoms of rhachitis, and gives to the chest the well-known *beaded* appearance, as it is called. The whole thorax is altered later, the sternum being carried forward, and the ribs are driven in laterally in expiration, producing the deformity known as the "pigeon breast." It is in the skull, however, that the most important bone changes take place—most important because I believe that rhachitis may be recognized, or at least suspected, before other symptoms have become marked, from the appearance of the skull alone. *The skull* in the large majority of rickety children *is too large*. The method of obtaining the measurement of children's heads I published some years ago in "The Pathologist." It is easily done and is quite accurate, and, at the risk of repetition, I will briefly describe the method here. The plan follows the rules laid down by Dr. Samuel Gee, of London, in an article on the "Shape of the Head looked at in a Medical Point of View," published in the "St. Bartholomew's Hospital Reports for the Year 1871." Dr. Gee states the rule to be that "in the head of the healthy child the ratio between the *greatest antero-posterior* diameter of the cranium and the *base-line* is as six to five." In other words, the cranium is about one fifth larger than its base. This rule I have tested for some years, and have measured many hundred heads according to it. I have found it remarkably accurate. Two principal varieties of large heads are met with in children—

the *cyclocephalæ*, or round heads, and the *dolichocephalæ*, or long heads. The first, or cyclocephalic head, almost always belongs to the *tubercular* child, and the second, or dolichocephalic head, almost as invariably belongs to the rhachitic child. This fact, it will be readily seen, is of great use. A child with a dolichocephalic head may, *prima facie*, be suspected of rickets; if, in addition, there be delayed dentition, there are ten chances to one that rhachitis is present. In examining the heads of children it is important to remember two things: first, that *shape*, not *size*, of the head is of most value; second, that long heads mean increase of the solid contents of the skull, and that round heads mean increase of the liquid contents of the skull. To ascertain the base-line and greatest antero-posterior diameters of the cranium, only a pair of calipers and a tape-line are necessary. The procedure is as follows: One leg of the calipers is placed upon the glabella, the other just beneath the tuber occipitale; the calipers is then removed carefully without displacing the legs, and the distance between the two points of the instrument is carefully noted. This is roughly the base-line of the skull. One leg of the instrument is now placed on the most prominent portion of the frontal bone, and the other leg upon the most prominent part of the occiput; the calipers then being removed, the distance between the two points will give us the greatest antero-posterior length of the skull. These two measurements must be in the proportion of five to six to each other; a very simple sum in proportion will, therefore, enable us to tell whether the head is abnormal or not. The following case may serve as an instance: C. L., a large, fat, dull-looking child, was placed in the Sheltering Arms Nursery. She was twenty-two months old, and had been nursed till her admission. Had delayed dentition, and some digestive disorder, not very great. Seemed in good health. Head measurements gave *base-line* $4\frac{3}{8}$ inches, and greatest length of cranium $6\frac{1}{4}$ inches. Applying the rule given, we find that in the normal head we have $5 : 6 :: 4\frac{3}{8}$ (base of patient) $: 5\frac{1}{4}$. Therefore the child's greatest length of skull should have been $5\frac{1}{4}$ inches, whereas it was $6\frac{1}{4}$—an inch larger than normal. She was pronounced rhachitic, and placed on appropriate treatment She got along well till about a month after admission, when she died of capillary bronchitis after less than twenty-four hours' sickness. The autopsy showed rhachitis existing, but apparently improving.

The symptom of craniotabes, described first by Elsässer, is found in a certain number of cases. It is, however, rare in my experience, though it seems to be frequent in Europe. It is a lesion of the bones of the skull, generally the occiput, and is detected by pressing with the tips of the fingers firmly on the head. If the condition be present, the bones yield slightly under the finger-tips, a small indentation being made. The spots where this change of bone takes place are small, and are due to imperfect ossification. The symptom may be met with as early as the sixth month, according to some authorities.

The last symptom which I shall notice is the delayed dentition. In a large majority of cases the evolution of the teeth is retarded till the tenth, twelfth, or fifteenth month, and after the teeth are cut they quickly blacken and crumble away. This symptom, however, unless accompanied by others, is of no great value, as delayed dentition depends on many other causes than rhachitis. The length to which this article has already extended itself will prevent me from dwelling on the treatment of rhachitis in detail. I shall, therefore, only outline briefly the management of this disease which I have found most successful. The treatment may be divided into the hygienic and the medical. Under the first head comes the supervision of the child's whole life. If the patient be at the breast, it should be immediately weaned if possible. The food should be personally inspected, both as to quality, quantity, and times of administration, no hearsay evidence being admitted; nor should the attendant confine himself to the giving of directions alone, but should see that they are properly carried out. If the starchy foods are given in excess, this should be corrected; if the variety of starch given be one difficult of digestion, another should be substituted for it, or a small quantity of malt added to the food, as is done in the Mellin's food. Finely chopped beef, fresh eggs, and peptonized milk should be added in suitable quantities to the child's diet. Saccharine matters should, as a rule, be avoided, as large quantities of sugar encourage fermentation and acidity and provoke diarrhœa, to which the patient is already too liable. Mutton-, chicken-, or clam-broth, with stale bread and fresh butter, may be allowed. The alvine discharges should be carefully inspected, and diarrhœa corrected by a small quantity of the bicarbonate of soda, administered in peppermint-water with a few drops of spirits of chloroform. This will also relieve the flatulency which is apt to occur. The clothing of the patient should receive the utmost care. Flannel should be worn next the skin winter and summer; in the latter a broad flannel bandage over the bowels is usually sufficient. The child should be bathed twice a day, and the body rubbed well with cod-liver or olive oil. The profuse perspiration may be checked by applying the tincture of belladonna—a teaspoonful to half a pint of water—several times daily to the skin. The patient must be taken into the open air regularly twice daily, no matter what the season is, provided it does not storm. It is far better, in my opinion, to take the chances of the child's taking cold than of his staying in-doors; very young or weakly children in cold weather can be wrapped up warmly and a bottle of hot water or a hot brick can be placed in the carriage with them, and they can be trundled about for an hour or so with safety on the score of getting cold. In the case of those who live in basements or northernly exposed rooms a change of residence is desirable. After indigestion has been corrected and the stomach gotten into good condition we may commence the exhibition of therapeutical agents. Cod-liver oil and the ferruginous tonics are the chief remedies to be employed. It is well to begin with a small dose of the oil, fifteen to twenty minims, as the power of digesting the fats is small in rickety children. This can be gradually increased. Iron, quinine, and the bitter tonics may be employed afterward as occasion demands.

ECLAMPSIA IN EARLY LIFE.*

By JOSEPH HEALY, M. D.,
BROOKLYN.

Diseases of children present peculiar difficulties to one who has studied the phenomena of disease in the adult. This arises from the fact that in the nervous system of the child the spinal predominates over the cerebral; and this is as it should be, since the different organs of the animal economy necessary to furnish nutrition for bodily growth and development are in active progress long before the infant formulates ideas, or really interprets fully the sounds that reach the ear, or the visions upon the retina.

The intense excitability of the nervous system in the healthy and robust child which gives to a trivial ailment symptoms of a grave disorder under the influence of enfeebling and chronic diseases, becomes diminished and disappears, so that we find a condition exactly opposite. Now, the nervous system has become insensible to the irritations of local ailments, and we search in vain for general manifestations. Ofttimes the local symptoms are so slight and obscure that they may easily escape our notice.

But, although a mere functional derangement may for a time excite such a tumult of disturbance in the general system as does a severe organic lesion, we must treat these general manifestations with a very careful appreciation of the susceptibility of the little organism to the shock.

And, on the other hand, we must consider the vital import of sufficient strength being furnished from without to the enfeebled one, who can not bespeak to the professional eye the expected manifestations of diseased action. Hence it behooves every person, who hopes to successfully treat the little ones in their many and varied ailments, to be cognizant of the dissimilarity of diseased action in the adult to the ever-changing and often contradictory phenomena of disease in children.

Let us consider for a few moments, and in a not far-extended or minute detail, one of the most common and often the most appalling morbid conditions in early life. I refer to eclampsia, or general convulsions.

The term "convulsions" is applied to different forms of spasmodic disease in which muscular innervation is deranged or perverted so that the movements become irregular and automatic and are no longer controlled by the will.

We may make several classifications of convulsions, according to our estimation regarding their nature or cause. Many of the French writers make three classes—idiopathic, sympathetic, and symptomatic.

The first two are not accompanied by any appreciable lesion of the nervous system, while in the third the convulsions indicate a sign or symptom of some disease of the nervous centers, as meningitis, tubercular disease, hydrocephalus, etc.

With all due respect for the French school, a classification into two varieties seems more reasonable and appropriate—namely, congestive and anæmic. Whatever the exciting cause, all convulsions may be classed under these two heads, and demand, if congestive, one line of treatment; if anæmic, another.

The susceptibility of the sympathetic and spinal nerves of early life to impressions and irritations of trivial character produce in a child of nervous temperament an ever-changing series of convulsions whenever the health becomes even slightly impaired; this susceptibility, as the brain becomes more and more developed and endowed with the control of later years, is gradually diminished and blunted, so that, as the years of infancy are passed, the effervescent display of nervous irritation fades into more stable manifestations of diagnostic value.

Even in the adult, when diseases producing hyperæsthesia of the spinal cord are present, all the varied reflex movements peculiar to the convulsed child appear.

In general, we may say that convulsions rarely prove fatal, yet every one who has practiced medicine has been summoned to his first case of a "baby in a fit." Perhaps his summons has filled him with apprehensions lest it prove his first certificate to sign, and render him open to criticism from the all-knowing neighbors in female attire. Should there be any before me who have not yet been summoned, let me say to him, Fear not, but go, and that, too, as quickly as possible; for, ten chances to one you will find the child first-rate, and hemmed in by ten or a dozen seemingly anxious individuals crowded around the poor unfortunate, absorbing all the oxygen the narrow bedroom may contain. If the convulsions have passed, even now you must do something and impress the bystanders with the importance of your presence. Give every one something to do and an opportunity to show their kindly interest and sympathy, while you see that everything is done to prevent a recurrence of the fit.

Should you find the child in the midst of the attack, act promptly and thoroughly; do nothing blindly, nor order any shot-gun dose to cover every possible cause of the disturbance.

First allay the spasm. Generally the relaxing properties of a hot mustard-bath will prove sufficient, with some pungent application to the nose, or the administration of the bromides, chloral or asafœtida, by the mouth or by enema. But, should the convulsions still continue and be severe, I invariably resort to the inhalation of chloroform and alcohol until the spasm be controlled and inquiries made in search of the cause, when the appropriate treatment may be chosen.

Many suggestions have been made as to the proper mode of treating severe spasms, each of which is claimed to be *the* one to follow. The above has proved adequate in my practice, but I can not but mention the hypodermic injection of chloral and the inhalation of nitrite of amyl with injections of morphia, in hopes that some one before me may have had experience with these agents that may prove of benefit for us to know.

There is no position in which a newly fledged M. D. may be placed, if he be possessed of a clear intellect and well informed and thoroughly disciplined in professional truths, where he may show the staying qualities of his judgment and tact as here, for the eyes of the neighborhood

* Read before the Medical Society of the County of Kings, June 16, 1885.

are upon him, and the verdict to be rendered will mean for him patronage or abuse.

First have confidence in your own ability, then you may inspire confidence in others. But the child still struggles. Let a hot bath be ordered, the room thoroughly ventilated, the pulse examined (if full and bounding, it will suggest congestion; while, if weak and feeble, anæmia or syncope), make inquiries concerning the attack, if this be the first, if the child has eaten anything unusual, if exposed to any malady, what acute specific diseases have been passed. Examine the head, whether cool or hot, the fontanelle protruding or retracted, the eyes congested or natural, the face flushed or pale, the gums red and swollen. Then strip the youngster and see if the legs are drawn up on the belly, the extremities cold or hot, the respiration deep or shallow, the belly tumid or lax.

By observing these different conditions, the line of treatment may be mapped out.

A pulse of 130, with accompanying headache, vomiting, and fever would indicate a digestive disturbance, and, if seen early, an emetic of ipecac, followed by a calomel purgative, will be of service, and later bismuth and soda. A slow and feeble pulse of 40 would suggest the advent of meningitis, where the bromides are of signal value.

If there has been diarrhœa, and the head cool, pulse weak, then a little brandy and water may be given; and even if the child be emaciated from disease, and the head be hot, the pulse rapid but small, we may still rely on brandy.

In some cases we find flatus in the bowels producing convulsions and the belly tumid; here friction with hot mustard-water, together with some carminative, as peppermint, anise, etc., should be given, rubbed up with sugar, and placed well back in the mouth.

As a rule, convulsions at the commencement of fevers do not indicate a grave prognosis, whereas if they occur later in its course they almost always suggest serious apprehensions.

In pertussis and diseases depending on a vitiated condition of the blood, where the convulsions follow closely one upon the other, our prognosis should be guarded.

When the fits are of short duration and moderate in intensity, with a natural, cheerful countenance soon returning, everything may be considered satisfactory; but if long-continued and occurring closely together, with a dull, heavy, anxious expression remaining, the danger is imminent.

Quite often much may be done when the attack is over to prevent a recurrence by avoiding the known causes, and by the soothing effects of the warm baths and bromides in children predisposed to this affliction.

But, notwithstanding the rapid strides in medicine, we may still have prodromata or none; the convulsions may be long or short, slight or severe, partial or general, recurring constantly or at long intervals, all of which points will require careful attention in each individual case, and tax our best endeavors to obviate, until we attain such perfect health that "there shall be no more an infant of days, nor an old man who hath not filled his days," but a blissful euthanasia await us all.

77 Gates Avenue, Brooklyn.

THE SALICYLIC-ACID TREATMENT OF THE INTESTINAL CATARRH OF INFANCY.*

By WILLIAM A. NORTHRIDGE, M. D.,
BROOKLYN.

During the summers of 1882, 1883, and 1884, while physician resident at the Seaside Home for Children, Coney Island, I became greatly impressed with the value of salicylic acid in the treatment of the inflammations of the intestinal canal, so common among young children during "the heated term." I venture this paper with the hope that it will lead many of you to give this remedy a fair trial in this class of diseases. The time is most opportune, as these maladies are now appearing among the little ones; are even now commencing their annual ravages. No effort should be spared to check them, more fatal, as they are, than any one of the contagious diseases so much feared. The importance of the successful treatment of these diseases is brought clearly before us when we examine the vital statistics of any large city and note the large increase of deaths among young children from them during the third quarter of the year. The death-rate in this city for one week of July, 1882, was over 52 per 1,000. Of the 603 deaths for the week, 262, or over two fifths, were from diarrhœal diseases among children under five years of age. Whether the diarrhœa be due to teething, improper food, action of heat on the sympathetic nervous system, or to any or a combination of conditions as exciting causes, there seems to be very little doubt but that the proximate cause is a pathological condition, probably due to microscopic organisms. I will not go further into the ætiology of these diseases, but will at once state that in salicylic acid we have a remedy of great value in their treatment; of course aided by proper nursing, dieting, and hygienic surroundings, without which medication would be valueless. I do not wish to detract from the value of opium in these diseases, cautiously and properly administered; but I do wish to protest against the careless routine use of the drug, because of its tendency to aggravate the passive congestion of the brain and the serous effusion into its membranes, which so often occurs and is so fatal. Salicylic acid is absolutely harmless and safe; children bear it very well. It may be administered to a weak infant in comparatively large doses, say one grain and a half every two hours, without danger. The formula used at the Sanitarium is in the following proportions:

℞ Acidi salicylici..... gr. iij;
Cretæ preparatæ..... gr. ij;
Syrupi simplicis..... ʒ j. M.

This much at a dose to a child of six months or over every two hours. As with other remedial agents, the medicine must be supplemented by proper diet, nursing, and, above all, by removal from the disease-breeding atmosphere of the city to the pure, fresh air of hills or sea-side whenever possible. The patient will begin to improve after the ad-

* Read before the Medical Society of the County of Kings, June 16, 1885.

ministration of a few doses, and in twenty-four hours the case generally will be markedly better. It will be noticed that the passages diminish in frequency, the watery, greenish-yellow stools being replaced by those commencing to have consistency and to assume a more natural color. In severe cases the passages become gradually less frequent. There is rarely a sudden cessation of the diarrhœa. From ten or a dozen movements on the day of beginning treatment, a reduction will be observed on the next day to five or six, with improvement in character. On the following day a further improvement, and so on until one natural passage is obtained. The following cases are from my case-book, and were kept separately from the regular books of the Home. They occurred among children sent to the Home during the summer of 1884. No choice was observed save that the very sick were chosen on their arrival at the Island.

Case I.—June 18th, Edward M., aged six months, sick two weeks. Three large, green passages to-day, containing undigested food and mucus. Child artificially fed; no vomiting; no fever; pulse weak. General condition poor. Ordered diet of boiled milk, lime-water, and arrow-root. Small doses of brandy as stimulant, and mist. salicylic., in 3 ss. doses, every two hours. 19th, child passed good night, is brighter; diarrhœa is less in quantity but continuing. 21st, considerable pain during night; diarrhœa still. 23d, six passages during day, less pain. 25th, baby much better; only one natural movement. 27th, he is much improved; has had no passage since 25th; sleeps well, no pain. 28th, passed good night; had one natural movement; no pain; baby brighter. Medicine withdrawn.

Case II.—July 14th, Edward C., aged seventeen months. Sick seven weeks. Three thin yellow passages to-day; no vomiting; great pain and restlessness at night; breast-fed. Gave mist. salicylic., 3 j doses, every two hours, and also three grains each of chloral hydrate and potassium bromide, with three min. of the compound tincture of ipecac in mixture at night, to relieve pain and restlessness. 15th, mother reports only one passage since yesterday; baby brighter; slept well. 17th, baby had perfectly natural passage; goes home well.

Case III.—July 15th, Robert B., aged eleven months; sick three weeks. Mother says daily average is twelve passages, greenish-yellow and watery in character. No fever. Pulse weak; no vomiting; considerable depression. Child breast-fed. Ordered mist. salicylic., 3 j, every two hours, and child to pavilion. 16th, five passages to-day; child brighter. 17th, one passage. 18th, one movement, natural; no vomiting; sleeps well; medicine withdrawn.

Case IV.—July 21st, J. T., aged nine months; sick two weeks; child teething; vomiting and diarrhœa; fifteen passages to-day; only little at a time, watery and green; fever and pain at night; pulse weak and rapid. Treatment: Gave two minims aromatic ammonia spts. every half-hour as stimulant; quieting mixture at night, and mist. salicylic., in 3 j doses, every two hours. 22d, 8 A. M., passed a poor night, vomiting and diarrhœa still continuing. Ordered treatment to be persevered in, and gave drop-doses of the wine of ipecac every hour, which efficiently controlled the vomiting; 5 P. M., same day, diarrhœa checked. 23d, baby had natural passage; no vomiting; discharged.

Case V.—July 28th, Jane M., aged five years and a half; sick four days; discharges dysenteric in character, containing blood and mucus; straining at stool. Gave patient a mixture containing in each drachm oleum ricini, ℥xv; tr. ipecac. co., ℥ij; vinum ipecac., ℥ij; glycerin, ℥x; mucilage acacia, q. s. 3j. Ordered diet of boiled milk and lime-water, crackers and rice. 29th, no improvement. 30th, none; changed the medicine, giving mist. salicylic., 3 j, every two hours. Improvement marked from soon after the taking of first dose. 31st, child had natural movement. In this case the inflammation was carried further than is usual.

Case VI.—July 29th, Fred. K., aged four years; sick one day. Has had several watery passages; no vomiting; child sleeps well. Gave mist. salicylic. in 3 j doses every two hours, and put child on diet of boiled milk and crackers. July 30th, twenty-four hours after commencing treatment, mother reported child well, and that he had had one natural movement.

Case VII.—July 30th, James C., aged sixteen months; sick four days. Several passages daily; watery, but no green color; vomiting; no fever; sleeps well. Ordered mist. salicylic., 3 j, every three hours, and diet of boiled milk and lime-water. July 31st, not so many movements; much brighter. August 1st, one natural passage; general health much improved. August 2d, discharged cured.

Case VIII.—August, 1884, M. O., aged two years and a half. Mother wrote me from country that child was having from five to nine greenish-yellow passages daily and losing flesh, when she had filled a prescription I had given her, at her request, before she left the city. This was mist. salicylic. She continued that, after a few doses of the medicine, the child commenced to improve and made a rapid recovery.

I might multiply cases from the books of the Home which, through the kindness of my friend Dr. Walker, are at my disposal, but I will refrain. Those which I have read are typical of the action and curative powers of the drug. Of the eight cases reported, all made a good recovery. The average duration of the disease from the giving of the first dose was two days and three quarters. Improvement was marked after the administration of the first few doses in all save Case I; and even in this case the diarrhœa was lessened and ultimately cured. The gradual cessation allows time for the clearing out of any of the products of inflammation or fermentation and the installation of healthy intestinal action.

Its principal modes of action are two:

1. By its anti-fermentative powers.

2. By the alterative medicinal quality inherent in salicylic acid, the salicylates and salicin in common.

1. By its anti-fermentative powers. Kolbe, Sternberg, and others have clearly proved that in salicylic acid we have an anti-putrefactive and anti-fermentative fully equal to carbolic acid. Dr. Sternberg says: "A two-to-four-per-cent. solution of salicylic acid will destroy the vitality of germs, while the presence of a one-quarter-to-one-half-per-cent. solution will prevent their development." Although it has not yet been proved, it seems highly probable that the pathological cause of these inflammations occurring during the summer months is a microscopic organism, which, upon the addition of heat, moisture, and improper food, enters into an active fermentative process. Salicylic acid destroys or inhibits this vegetable organism, upon which the activity of the process depends.

But, says some one, The formula which you have read to us, is there salicylic acid there or a salt? I answer, A salt for the most part; but many particles of free acid are scat-

tered through the mixture. Tested with litmus-paper, it proves neutral, save that the blue litmus is dotted red by particles of free acid. On evaporating and rubbing dry residue on litmus-paper and then wetting the paper, gives an acid reaction. It is the amount of free acid in the mixture which accomplishes the checking of the fermentative process. This it does by its presence at the seat of disease without entering the circulation.

Dr. M. Wagner writes of salicylic acid that "its use is highly promising as a prophylactic in all diseases in which it is believed that the morbid processes are connected with microscopic organisms." He commends its administration in all cases where fermentative changes occur in the alimentary canal, because it may be administered in large doses. Dr. Sternberg writes: "Dr. Keating, of Philadelphia, strongly recommends salicylic acid in the treatment of the acid diarrhœas of children. In this case there can be little doubt that the benefit derived from its use is to be ascribed to its destroying or restraining the vital activity of the living ferment to which the acid fermentation is due."

Its second mode of action is through the blood. We know empirically that in salicylic acid, its salts, and in salicin, we possess medicines which show the containing of an inherent, valuable medicinal quality which we all recognize. We know that they have an alterative effect upon mucous surfaces, and in this fact probably lies an explanation in part of their valuable medicinal action in these diseases. While the healthy bowel is enabled to withstand the presence of a combination of disease-breeding elements, its powers of resistance being at par in consequence of good nerve action and muscular tone, the deterioration of these by the action of heat on the nervous system, the local action of heat, and the imbibition of improper food, reduce this disease-resisting power until out of lowered healthy action come diseased conditions. Further than this we can not go in explanation, for we are in ignorance of the exact mode of action; but the fact of its curative powers is known, and that is the main point. Dr. S. W. Smith, in the "British Medical Journal" for 1884, vol. ii, says: "Willow charcoal (salicin) is of great value in the treatment of diarrhœas." He got the idea from Liverpool sea captains, who use it. "Eminent medical men" whom he consulted thought "that it was of great value in fermentative diarrhœas."

Lawson (Heuseman, note, page 773, *supra*) advises "the use of salicin in six-to-eight-grain doses, thrice daily, in cases of summer diarrhœa resulting from direct action of heat on the nervous system."

Dr. J. B. Mattison, in the "Medical and Surgical Reporter," 1873, advises the use of salicin in cases of diarrhœa resisting other modes of treatment. In all cases where salicin is used, the curative effect is due to its second or alterative medicinal action, and not to any germicidal effect. And now, in conclusion, I will state:

1. That in salicylic acid and its derivatives we have most valuable remedies in the treatment of diarrhœas, and especially in those occurring among children during "the heated term."

2. That its remedial powers are due, first, to the antifermentative powers of the acid acting locally; second, to an alterative effect through the circulation.

3. That it is an efficient substitute for opium in those cases where that drug is contra-indicated.

A CASE OF CÆSAREAN SECTION.*

By CHARLES JEWETT, M. D., Brooklyn,
PROFESSOR OF OBSTETRICS IN THE LONG ISLAND COLLEGE HOSPITAL.

The subject of this report was a woman of about forty-six years, of Irish birth, the mother of ten children—the youngest four years of age, the eldest seventeen. She presented herself in the out-door department of the Long Island College Hospital, at the clinic of Dr. Ernest Palmer, in August, 1883. Dr. Palmer made the diagnosis of pregnancy, with cancer of the cervix. At the seventh month of gestation she entered St. Mary's Hospital, service of Dr. John Byrne. Dr. Byrne proposed amputation of the cervix with the galvano-caustic loop, but the patient declined the operation and left the hospital. December 9, 1883, was admitted to the lying-in department of the Long Island College Hospital. At this time she was weak and anæmic from frequently recurring hæmorrhages, complained of constant pelvic pain, and slept little or none except by the aid of opium. During the waiting period her temperature did not exceed 99° F. The pulse ranged from 94 to 108. The malignant growth now involved the supra-vaginal portion of the cervix, and had commenced to invade the vagina.

Labor-pains began at 11 A. M., December 26th. At 8 P. M., though the pains had become severe, the cervix remained hard and unyielding, barely admitting the finger. The membranes were still intact. Delivery by the natural passages was evidently out of the question. The hospital staff concurring, it was therefore determined to deliver by Cæsarean section. This operation was accordingly done in the presence of the hospital staff and a number of students, Dr. Skene, Dr. Palmer, and Dr. Thallon assisting. The patient had been removed from the maternity to a large, well-ventilated ward, previously disinfected. The abdominal surface in the field of operation was shaved, cleansed with soap and water, and then sponged with ether and with the bichloride solution. When the patient had been placed under ether, the abdominal incision was made through the linea alba, from the umbilicus to a point about two inches above the pubes. A loop of stout rubber tubing was then passed over the uterus, and slipped down behind it till it encircled the cervix. This constrictor was drawn taut enough to control the blood supply, tied in a single knot, and the knot held with a large Péan forceps. The uterus was drawn up into the abdominal wound by traction upon the constricting tube. A very short incision was made in the uterine wall just above the cervix. A few light touches of the knife uncovered the membranes, the muscular tissues retracting from the line of incision. A blunt-pointed bistoury was plunged through the membranes, and the incision rapidly extended upward to a point short of the fundus. The fœtal head was immediately seized with both hands, and the child, a living male of seven pounds and a half, extracted. The uterus instantly contracted, partially expelling the placenta through the wound, and at the same time it was tilted out through the abdominal incision by traction on the constricting tube. The membranes were now carefully detached. The uterine cavity was cleansed and well mopped with a sponge wet with the bichloride solution, and a pencil of iodoform was deposited therein. A utero-vaginal drainage tube, of half-inch perforated rubber tubing, was passed down through the cervix,

* Read before the Brooklyn Pathological Society, February 26, 1885.

terminating below at the vulva and above near the fundus. The uterine wound was closed with deep and superficial sutures of sublimated silk. The deep sutures included the entire thickness of the uterine wall, except the decidua. The superficial sutures were passed as follows: A fold of peritonæum was lifted near the edge of the uterine incision, and parallel with it. The sutures were passed transversely through this fold, and through a similar fold on the opposite side of the wound, thus twice perforating the peritonæum on either side of the incision. On tying the sutures, therefore, two free surfaces of peritonæum were brought in contact. The uterus, which had been drawn up through the abdominal incision on extraction of the fœtus, was now dropped back into the abdominal cavity. But slight oozing of blood occurred into the vagina on removing the constricting tube. The peritonæum was cleansed with hot aseptic sponges, a drachm or two only of fluid being obtained. The abdominal wound was closed with sublimated silk sutures. A long, curved glass drainage-tube was passed down beside the uterus into Douglas's pouch, emerging between the sutures of the abdominal wound. A dressing of sublimated cotton was applied over the abdomen, and marine lint to the vulva. The mouth of the abdominal tube was closed with an antiseptic sponge and rubber tissue in the usual manner. A partial antisepsis was observed throughout, a five-per-cent. solution of carbolic acid being used for instruments and a 1-to-1,000 bichloride solution for other purposes. The uterus, while turned out of the abdomen, was enveloped with towels wrung out of hot disinfectant solution, frequently changed, and the upper portion of the abdominal incision was protected with similar covering to prevent prolapse of intestines. The patient was removed from the table with a pulse of 120. An hour later, pulse 110, temperature 99°. There was little or no vomiting after the anæsthetic. During the first twenty-four hours the patient was comfortable, with the aid of occasional small doses of morphia, upon which she had already become dependent, and recovery seemed probable. At the end of that time the abdominal tube showed accumulation of fluid in the peritoneal cavity, at first clear and subsequently turbid, and the temperature rose to 102·6°. Death followed in forty-five hours after the operation.

A complete autopsy could not be had. The abdominal wound, which had united throughout, except at the seat of the drainage-tube, was reopened, and the uterus and appendages removed. The peritonæum was everywhere injected and flecked with fibrin—diffuse peritonitis. The cavity contained a small accumulation of turbid serum. The uterine incision had united throughout from the decidual to the peritoneal surface. Its muscular structure, but for the malignant growth, was apparently normal. The cavity contained a firm blood-clot, perfectly sweet, and still yielding the odor of iodoform. The peritonitis was thought to be due to an outbreak of erysipelas which had occurred in the general hospital service a few days before the operation, and which had also infected a maternity patient delivered on the same day with the Cæsarean case. The uterus as presented, after lying several months in alcohol, measures in length seven inches on its posterior and seven inches and a half on its anterior surface externally, and in width four inches at the level of the Fallopian tubes. The anterior wall shows the line of incision three inches and a half in length, and securely closed throughout. The direction of the incision is slightly oblique, indicating a slight right obliquity of the uterus at the moment of incision. Twenty deep and superficial sutures can be counted, though there are probably others that have escaped detection.

Remarks.—The statistics of the Cæsarean operation in this country, thanks to the researches of Dr. R. P. Harris, are well-nigh or quite complete. The case now reported, writes Dr. Harris, "is the one hundred and thirty-fourth in the United States. It is the seventh hospital operation, and is the only case of Cæsarean section in this country for cancer of the cervix.

"Of the one hundred and thirty-four women, fifty-three were saved. All the hospital operations were fatal.

"Of seven Cæsarean operations in the United States since April 6, 1884, all were fatal to the mothers, and all but the above case fatal to the children.

"There have been thirty-three operations in the last decade, and twenty-five of them fatal; four of the latter in New York State. Thus the percentage saved has greatly fallen off by the work of ten years, when it should have increased. The great fatality was due mainly to delay, the women being worn out with labor before the operation.

"We now number in North America, the United States included, one hundred and forty-three operations, with sixty women saved.

"In Great Britain, up to May, 1879, there had been one hundred and thirty-two Cæsarean cases, of which twenty-three were saved and one hundred and nine lost.

"Seventy-seven children were saved and fifty-five lost. In twelve of the above cases the operation was done owing to cancer of the cervix. In this number four women and ten children were saved. Thus it will be seen that in England operations for cancer have been much more successful than for any other form of obstruction."

The general record of Cæsarean section, however, does great injustice to its capabilities. Dr. Lusk has shown that the mortality of the Cæsarean operation has been due in a great part to untimely interference and to other causes not inherent in the operation itself. In cases operated early, the statistics of Dufeilhay, cited by Dr. Lusk, show eighty-one per cent. of women saved. In another series of sixty-one operations in rural districts there were more than seventy-eight per cent. of recoveries.

But even the best results thus far obtained are, with very few exceptions, those of the unimproved operation. The recent improvements in the technical methods of operating give promise of still better results. A prominent cause of death after Cæsarean section has been the tendency of the uterine wound to gape, thus permitting the escape of lochia into the peritoneal cavity. Various plans of treating the uterine incision have been proposed with a view to obviate this danger. Among them may be mentioned the methods of Sänger, Kehrer, Pillore, Frank, and Cohnstein, which, with others, will be found fully discussed in a recent paper by Dr. Garrigues.*

The plan pursued in the foregoing case has the advantage of simplicity, and is doubtless no less effectual than the more elaborate method of Sänger.

The constrictor relieves the operation of a formidable complication and adds to the chances of success, for, while hæmorrhage is rarely of itself alone the cause of death, it contributes to the fatal issue.

The large proportion of successes in rural districts

* "Amer. Jour. Obstet.," April, 1883, *et seq.*

shows what is possible for antiseptics. Yet it is doubtful if any thoroughness of antiseptic detail can justify operating in a hospital.

Germany is already beginning to reap the fruits of the improved technique, Leopold, of Dresden, having saved three women with their children by the Sänger method.*

In timely operation with the precautions now thrown about ovariotomy, Cæsarean section should not fall much behind the record of other laparotomies.

PULMONARY GANGRENE.†

By ELIZA M. MOSHER, M. D.,
BROOKLYN.

Mary J. S., committed to the Massachusetts Reformatory Prison for Women for drunkenness, May 6, 1879; age, twenty-six years; single; occupation, general housework; was healthy as a child; became intemperate at eighteen, and acquired syphilis. Had been sentenced many times to the Boston House of Industry for drunkenness.

When examined, on admission to the prison, she was found to be anæmic and generally out of health. She said she had coughed a good deal since the night of her arrest, at which time she had lain several hours on the ground in a drunken stupor. She was removed to the prison hospital on the 8th of May, two days after her arrival. Her face was then pale and pinched, cough incessant, pulse weak, temperature and respirations normal. A few coarse râles were heard in various parts of the chest, but no other physical signs of disease were discovered. On the 10th of May her temperature rose to 100·2°, and on the 11th to 102·4°, with a pulse of 90 and respirations 24 a minute. This condition continued until the 15th, when the temperature slowly declined to 99·6°, and the pulse became normal. On the 18th the sputum, which up to this time had been scanty, became copious and consisted of frothy mucus of strongly putrescent odor. The same odor was observed also when coughing occurred without expectoration, and also on forced expiration. She complained of great soreness in the left sub-scapular region, increased greatly by the effort of coughing. Dullness on percussion in this region now became manifest, and fine mucous râles were heard. Breathing grew more rapid, and on the 23d the temperature again rose to 101·6°. The odor of the breath was such as to be tolerated only by the freest ventilation combined with the use of bromine and other disinfectants.

On the night of the 29th of May she raised a small quantity of what appeared to be dark blood, after which amphoric respiration was heard below the left scapula, extending into the infra-axillary region. During the week following the patient seemed better, temperature and pulse returned to the normal, respiration became easier, and the odor of the breath less fœtid. On the 7th of June, however, the temperature rose quite suddenly to 102° and did not again decline until the day of death; the pulse at no time went above 96. Respiration again became very rapid and somewhat labored. The cough was incessant when not quieted by opiates; sputum consisted of a frothy mucus containing flecks of a brown putrescent substance which settled to the bottom of the cup, in quantity from eighteen to thirty-two ounces in the twenty-four hours; its odor was horrible in the extreme.

On the night of June 15th, five weeks from the commencement of the attack, she again raised several ounces of dark-colored sputum, followed by a small amount of fresh blood. The dullness on percussion now extended higher, and amphoric breathing was heard over the entire region below the spine of the scapula; meanwhile a fairly good vesicular murmur was heard in every other part of the chest.

On the 20th she again raised several ounces of semi-solid putrescent matter, followed, as before, by a little fresh blood. From this time she rapidly lost strength, and death occurred, apparently from exhaustion, on the 30th of June—fifty-three days after admission to the hospital. The treatment adopted was from the first stimulant and tonic (mainly quinine and brandy), with inhalations of turpentine, compound tincture of benzoin, carbolic acid, etc. The latter part of the time morphine was given freely to check the cough and give rest.

A post-mortem examination was made four hours after death with the following result: Rigor mortis not established; skin pale and bloodless; body not greatly emaciated; adipose and muscular tissues apparently normal. Pericardium and heart normal; valves of heart healthy. Right lung slightly catarrhal, otherwise healthy. Pleura of left lung was much thickened; its visceral and parietal layers were here and there firmly bound together by adhesive bands, and the interspaces thus formed were distended with putrescent gas, which escaped with a report upon puncture. Upper lobe catarrhal; superior portion of lower lobe consolidated, while of the most dependent portion behind nothing remained but a gangrenous, sloughing mass. There was loss of tissue along the lower margin of the lung anteriorly, giving it the appearance of having been gnawed. Here and there a patch of cicatricial tissue told the story of attempts at repair. No other cavity of the body was opened.

In the case before us, gangrene of the lung was doubtless the result of embolism and infarction. During the process of softening of the gangrenous tissue, communication with a bronchus was established, and, as it became liquefied, it was expectorated.

An attempt at cicatrization was made again and again, but each time enough of the putrid ferment remained to renew the gangrenous process.

After a discharge of the necrosed portion the temperature and pulse declined to the normal, the breath lost much, though not all, of its putrescent odor, the cough lessened, and the patient imagined herself recovering, only to be disappointed when the inflammatory process again was aroused and another slough went through the process of separation.

The hæmorrhage which followed each discharge came, doubtless, from vessels or granulations on the line of demarkation.

"Gangrene of the lungs consists in death of lung tissue associated with putrefaction, owing to the admission of air."* Since the time of Laennec two forms have been described, the circumscribed and the diffused; of these, the former occurs by far the more frequently. Fortunately, gangrene of the lungs is not a common disease. But two cases have occurred at the Massachusetts Reformatory Prison for women since its establishment in 1877. At the Boston House of Industry, on Deer Island, no cases have been reported during that time, and but two have occurred at the Boston House of Correction—institutions which together represent about two thousand persons.

* Dr. Harris writes, since this paper was written, that Germany has had eight operations after Sänger's method of suturing, two modified (without the resection), and has saved six women and eight children.

† Read before the Brooklyn Pathological Society, February 26, 1885.

* Hertz in von Ziemssen's "Cyclopædia."

The disease is said to appear most often in the insane, in drunkards and epileptics, and in children. A low state of nutrition with weak heart-action is a predisposing cause. An interruption of the blood-current, the passage of foreign bodies into the air-passages, and traumatic influences, may be numbered among the chief exciting causes of the disease. Obstruction of the blood-current may arise from the pressure of pneumonic inflammatory exudate, or hæmorrhagic blood retained in the air-cells and intercellular tissue. It is, however, most often due to the passage of an embolus into the pulmonary circulation. A minute vegetation from the valves of the right heart, a tiny clot picked up somewhere in the venous circulation, or a fragment of a thrombus from some purulent center, finds lodgment in a pulmonary vessel. According to Cohnheim, rupture may not occur at once; the walls of the emptied vessel become impaired through lack of nutrition, so that, when they are again filled by means of the collateral circulation, they are too weak to bear the strain, and rupture occurs. The infarction thus produced may not extend beyond a single lobule, and it may exceed the size of a hen's egg. Its favorite seat, and consequently that of circumscribed gangrene, is the lower border of the inferior lobes posteriorly (most often the right).

It would seem that gravitation, as well as the anatomical arrangement of vessels, has somewhat to do with the site it chooses. The extravasated blood fills the air-passages as well as their interspaces; contact with air rapidly produces decomposition, and the process is doubtless hastened by the development of vegetable parasites in this most fertile soil.* The irritation produced in the adjoining healthy tissue by the presence of a putrefactive ferment results in localized inflammation which hastens the process of separation.

Occasionally the gangrenous slough is expectorated *in toto* and cicatrization occurs with recovery; but more often (as in the case which forms the basis of this paper) the putrefactive ferment is never entirely removed, and repeated attacks of inflammation occur, producing consolidation of lung tissue, which, added to the poisonous influence of the gangrene, rapidly exhaust the strength of the patient and ultimately cause death. Hæmorrhages frequently occur, and are due to the sloughing of blood-vessels, or the blood may ooze from wounded granulations on the line of demarkation. If the infarction is located near the surface of the lung, the pleura participates in the inflammatory process. Adhesions and thickening of the membrane follow, and sometimes *it* also becomes gangrenous.

The physical signs of infarction are so obscure that an early diagnosis is rarely made. Dullness on percussion over a limited area, with an irritative cough, accompanied by weak pulse and general malaise with pinched features, is usually all that is observed until the inflammatory fever arises and the breath becomes putrid. One needs but a single whiff of this sickening odor to render a diagnosis easy. It differs as widely from the fœtor observed in some cases of phthisis, and even from that of bronchiectatic cavities, as does the odor of necrosed nasal bones from that of ill-smelling mucus.

Foreign bodies, as particles of food, etc., are sometimes sucked into the air-passages, especially in the artificial feeding of lunatics and paralyzed persons, and, by their rapid decomposition or mechanical pressure, set up putrefactive changes in the lung.

Gangrene from injury to the lungs, such as gunshot wounds, stabs, etc., occasionally occurs, and it has been known to result from severe contusions of the thorax, causing an effusion of blood into the lungs. The diffuse form of gangrene frequently succeeds the circumscribed; it also occurs as a sequel to pneumonia and other diseases. In this variety the lesion is most often found in the upper lobes, and may involve a large portion of a lung.

The sputum in gangrene of the lungs is usually copious, owing to the irritation of the bronchial mucous membrane by the presence of putrid matter. It at first consists of a frothy opaque mucus; subsequently it becomes ash-gray, green, or brown, and separates into two or three distinct layers, the lower of which contains solid blackish particles with soft yellow or brownish lumps, varying in size from that of a hemp-seed to that of a bean. Under the microscope the blackish flakes have been found to be shreds of lung tissue which have undergone disorganization. They are made up of granular matter and pigment cells, with here and there a few elastic fibers. The soft yellow lumps consist of fat globules with crystals of margaric acid.

Leyden and Jaffé* instituted a careful chemical examination of the sputum of gangrene, and found the products of the decomposition of albuminous and fatty tissues—viz., myosin, leucin, margaric acid, traces of glycerin, volatile fatty acids (mainly butyric, from which it largely derives its odor), sulphide of ammonium, etc.

Up to the present time no treatment has proved effectual in any number of cases. But few remedies administered by the stomach, other than tonics and stimulants, have been of any use; of these, carbolic acid and creasote have their advocates, and Dr. Henry I. Bowditch, of Boston, has had good results from the use of liquor sodæ chlorinatæ. Medicines used by inhalation, as recommended first by Skoda in 1852, promise better results, but up to the present time have been efficacious only in the most favorable cases. We have reason to hope, however, that, by means of the "pneumatic differentiator" of Dr. Herbert Williams, of Brooklyn, a new era in the treatment of pulmonary gangrene, as well as in other diseases of the lungs, has begun. There seems to be no doubt but remedies are carried more deeply into the lungs by its use than by any other known method, while the air imprisoned by an infarction or by abnormal secretions becomes by its expansion a powerful *vis a tergo* for the removal of obstructing substances. Dr. Williams reports the treatment of a case of "necrosis of lung caused by pressure of pleuritic fluid." As no mention is made of a putrescent odor, we can not consider the case one of gangrene. The results of treatment, however, were in many ways satisfactory and suggestive.

* *Leptothrix pulmonalis*, according to Leyden and Jaffé.

* Von Ziemssen's "Cyclopædia."

Death occurs early in nearly all cases of diffused gangrene of the lungs. The circumscribed form is usually more slow in its destructive action, and patients sometimes live months. Recovery takes place in a limited number of cases, but the prognosis is always a grave one.

URETHRAL STRICTURE; CYSTITIS; PYELONEPHRITIS; URINARY EXTRAVASATION.*

By CHARLES N. DIXON JONES, M. D.,
BROOKLYN.

S. S., aged fifty-five, married, by occupation a wheelwright, was admitted into the wards of the Brooklyn Hospital, June 16, 1884, in a condition of exhaustion and stupor. The following history was obtained: Early in life the patient contracted a gonorrhœa, which ultimately resulted in a troublesome stricture. From that time he has had much and increasing difficulty in passing his urine. In 1870 he had an attack of acute cystitis; at that time there is said to have been some paralysis, the exact nature of which could not be ascertained. In 1882 he had another attack of cystitis, since which time his difficulty in urinating has steadily increased. Two weeks ago, while thus suffering, he was exposed to cold and wet; since then he has had to strain a great deal in order to pass his water at all.

Some uneasiness in the region of the perinæum was complained of, and a slight swelling was detected in this locality. The scrotum was of a red color and shining in appearance. The prepuce was long, and so contracted at the orifice that it could not be retracted over the glans penis. At the meatus a condition of hypospadias was observed. On passing the finger into the rectum, the prostate was found to be somewhat enlarged.

The urethra was first examined with a fair-sized instrument. But it was only after considerable difficulty that I succeeded in passing the finest whalebone bougie. By passing one bougie after the other, and leaving them in position until all the follicles were filled, I finally succeeded in passing one into the bladder. Along the side of the instrument, which was tied in the bladder, the urine slowly dribbled away. In a short time the patient succeeded in withdrawing the instrument from the bladder. The urine was found to contain albumin and pus in large quantities.

June 17th.—By the use of stimulants and proper nourishment the patient's general condition had improved to some extent. Scrotum now much swollen and œdematous; perineal swelling quite conspicuous. The patient was examined by Dr. Speir, the attending surgeon, who kindly requested me to operate as soon as possible.

After careful ætherization, the patient was placed upon the operating-table. A filiform bougie was passed into the bladder and the strictures divided with a Maisonneuve's urethrotome. A steel sound was then introduced and external perineal urethrotomy performed. A deep linear incision was made in the center of the perinæum, and a cavity, filled with pus and urine, laid open and its contents evacuated. All sinuses and abscesses were freely laid open and washed out with warm carbolic solution. A soft catheter was then passed through the perineal wound into the bladder, and retained there. A drainage-tube was inserted to the bottom of the abscess cavity and left *in situ*. The scrotum was freely incised in several places. Dressings saturated with a solution of liquor sodæ chlorinatæ were applied. The patient was then placed in bed surrounded with hot bottles, and freely stimulated. The abscess cavity was washed out every four hours with 1-to-100 warm carbolic solution. The urine passed away through the perineal wound, although small in quantity.

The patient rallied somewhat after the operation, and, for a time, seemed greatly improved. On the 21st the scrotum was discolored and gangrenous. Patient dull and stupid; skin cold and clammy.

On the 23d, condition much the same. Temperature 97·5° F.; pulse quick and not so strong. Perineal wound presents an unhealthy appearance.

On the 25th, A. M., quite feeble; does not take his nourishment. Freely stimulated. P. M. Unconscious; pulse very feeble; coma became profound, and remained so until death, which occurred at 3.45 A. M., June 26th.

Post-mortem Examination.—At the autopsy, eight hours after death, the body was found somewhat emaciated.

Lungs.—Right, œdematous. The left lung was intensely congested and œdematous; bronchial tubes contained frothy mucus and pus. Heart normal in size; aortic valve thickened and insufficient from old endocarditis; mitral valve thickened; liver small and cirrhotic. Left kidney small, markings indistinct, pale in appearance; capsule non-adherent. Right kidney very small; it measures one inch and a half in length by three quarters of an inch in diameter; weight, two ounces and a half; substance mostly replaced by fat; several small abscesses in substance of kidney-tissue proper. Pelvis of both kidneys intensely congested and covered with pus. Both ureters were dilated, with thickened coats.

Upon microscopical examination, the kidneys presented the lesions of chronic croupous nephritis, with waxy and fatty degeneration. In the smaller kidney all the tissues had undergone complete atrophy. The glomeruli had disappeared or were replaced by fibrous tissue. In the larger kidney, in addition to the atrophied portions, there were certain districts where there had been an increase in the amount of connective tissue, thus constituting a true hypertrophy.

Bladder.—Cavity small and contracted; hardly has a capacity of four ounces. Walls very much hypertrophied; the mucous membrane thickened, thrown into ridges, which run in various directions, forming crypts which contain pus. Surface red and deeply congested, covered with pus. The condition indicated long-continued chronic cystitis.

Urethra.—By laying open the urethra, two strictures were found—one about three inches and the other five inches from the meatus. Prostate enlarged.

In the floor of the urethra there is a small opening which communicates with an abscess cavity in the perinæum three inches in diameter. Scrotum in a sloughing condition.

The follicles in the membranous portion of the urethra are inflamed, and from these cavities a drop of pus may be pressed. One, much larger than the rest, presents an opening through which a probe may be passed into the abscess cavity.

The case presented is of interest chiefly from a pathological point of view, for, as is demonstrated by the autopsy, when the patient came under observation the morbid changes in several of his most vital organs had advanced to a stage where they were beyond the reach of surgical skill.

In tracing the pathological sequence in the above case, several points are to be noted:

1. The beginning of his trouble was a gonorrhœa acquired in early life.

Sir Henry Thompson claims that the urethra is not a

* Read, with presentation of the specimens, before the Brooklyn Pathological Society, February 26, 1885.

tube, but a continuous closed valve. Its length renders it liable to disease and accident—"the price—and a heavy one, let me tell you—which the male pays for his specially distinguishing feature."

Remembering this fact, it is easy to see how an inflammatory process affecting this passage, which is so richly supplied with blood and nerves, leads to secondary pathologieal results which affect the prostate gland, bladder, ureters, and kidneys. The testes, penis, seminal vesicles, perinæum, and rectum share, not unfrequently, in the same pathologieal process. The urethritis destroys the natural elastieity of the canal. The elastieity of the urethral walls being thus lost, the urine ean not escape so readily, hence the resulting hypertrophy of the bladder. The bladder which has undergone hypertrophy can not eompletely empty itself. It is estimated by Ultzmann that a patient who, at twenty or thirty, has a residue of only 20 c. c. remaining in the bladder after urinating, will have from 200 c. c. to 300 c. c. at fifty, with aecompanying hypertrophy. The urine whieh remains is mingled with pus-corpuscles, and undergoes alkaline fermentation. Bacteria are developed, and the inflammation is liable to extend through the ureters to the kidneys.

2. The specimen presented demonstrated the extremely unhealthy condition of the kidneys. The nephritis from which the patient suffered must have been of long standing. We all know the extremely unfavorable influence which any form of nephritis exerts upon all operations on the urinary organs.

In considering the kidney lesion in this case, the complicating cardiac and hepatic lesion must be taken into consideration. The condition of the heart can not be considered merely an accidental complication. By some writers on this subject the cardiac complieation has been conconsidered the most important part of the disease. Dr. Mahomed speaks of cases of Bright's disease which die without nephritis. He drew attention to the faet that Bright's disease is often a general and not a simply local disease.

From the history of the case presented, it would appear that the stricture of the urethra was an efficient cause in producing the renal disease, yet the form of nephritis found is not such as we usually meet with in such cases. The question arises, Was not the kidney lesion independent of the urethral stricture? Opposed to this view is the absence of cardiac hypertrophy and the eondition of the bladder and ureters, whieh correspond to the conditions that are frequently found, after old neglected urethral strieture.

The theories in regard to the interdependence of renal and cardiae disease are too numerous, complicated, and unsettled to allow of discussion at this time. The sequence of events in this ease seems to have been urethral strieture, cystitis, pyelitis, and nephritis.

3. Dittel, of Vienna, was the first to show that in cases where death resulted from urinary extravasation the opening by which the urine slowly infiltrated the loose conneetive tissues was through an ulcerated follicle of the mucous membrane of the urethra. Prof. Otis has fully elaborated this theory, and shown the influence whieh a stricture of either large or small caliber exerts in producing this pathological result. A stricture so slight that it would admit the easy passage of a catheter would be sufficient to retain the organic *débris* of a person suffering with lithiasis; or, from increased urinary irritation at a point of strieture, a folliculitis is set up which may eventually result in suppurative inflammation and perforation of the urethral wall. This is probably what oeeurred in the case above recorded.

In the history of this case, although obtained with difficulty, there is nothing to indicate that a sudden rupture of the urethral wall had taken place, such as sometimes occurs behind a stricture during some violent act of straining, with extensive extravasation of urine into the intercellular spaces.

NOMENCLATURE OF AURAL DISEASES.

By SAMUEL SEXTON, M. D.,
SURGEON, NEW YORK EYE AND EAR INFIRMARY.

Introductory Note.—I have been requested to publish for the use of others the following nomenclature, which was prepared for my own convenience. In the arrangement no little difficulty was experienced in reconciling the opinions of various writers in respeet to certain affections of the ear, but it is believed that the classification, imperfect as it neeessarily must be, may afford some assistance to others who, like the writer himself, have felt the need of such a work of reference. Not to mention minor defects, it is to be regretted that the comparatively undeveloped pathology of the inner ear prevents a complete classification of its diseases. In the final arrangement of the work of elassification I have been very mueh assisted by Dr. Robert Barclay, Assistant Surgeon, New York Eye and Ear Infirmary.

DISEASES OF THE EAR.

EXTERNAL EAR—AURICLE.

I. *Abnormalities.*
- *a.* Arrested development.
  1. Abnormal position.
  2. Absenee of auricle, or parts of auricle, and altered shape, as lapping, eonvolutions, due to absence of cartilage.
  3. Microtia.
  4. Congenital fistula.
- *b.* Exeessive development.
  1. Plurality.
  2. Abnormal enlargement.
  3. Polyotia (Auricular appendages).
  4. Reduplication.
- *c.* Irregular development (?).

II. *Cutaneous Diseases.*
- *a.* Callosities.
- *b.* Comedo—Acne punctata [Sebaceous tumor?].
- *c.* Dermatitis.
- *d.* Eezema.
- *e.* Erysipelas.
- *f.* Erythema, Flushing.
- *g.* Furunele, Abscess.
- *h.* Gangrene [from Embolism, Low Fevers, or Freezing].

i. Herpes zoster (Auriculæ idiopathica).
j. Hydroa.
k. Ichthyosis (congenita).
l. Intertrigo.
m. Keloid.
n. Leprosy.
o. Lupus (erythematosus, maculosus, exulcerans).
p. Molluscum fibrosum.
q. Myxoderma [a neurosis whose ætiology is undetermined].
r. Nævus.
s. Pemphigus gangrenosus.
t. Pernio [Frost-bite].
u. Phagedæna [Cancrum oris].
v. Phlegmon (acute, chronic).
w. Syphiloderma (erythematosum, papulare, tuberculare, pustulare, squamosum, serpiginosum, ecthymatosum, ulcerativum, nodosum).
x. Tophi.
y. Trichophytosis [Ring-worm].
z. Ulcer.

III. *New Growths.*
a. Angioma—Glandular hypertrophy.
b. Cavernous tumor.
c. Cyst (dermoid, sebaceous). Atheroma, cornu. [Comedo? Acne punctata?]
d. Cornu. [*Vide* Cyst.]
e. Epithelioma.
f. Fibroma.
g. Fibrosarcoma.
h. Lipoma, Steatoma [Atheroma?].
i. Myxofibroma.
j. Myxosarcoma.
k. Nævus vascularis [maternus].
l. Sarcoma.
m. Hæmatoma. [*Vide* Wounds and Injuries.]

IV. *Wounds and Injuries.*
a. Cleft of lobule [by ear-ring].
b. Lacerated wound.
c. Contused wound. Hæmatoma [Othœmatoma].
d. Incised wound.
e. Punctured wound.
f. Shot wound.
g. Effects of heat.
1. Burns.
2. Scalds.
h. Effects of cold.
1. Frost-bite.
2. Gangrene.
3. Chilblains.
i. Effects of mineral and vegetable irritants.
1. From acids.
2. " austic alkalies.
3. " metallic compounds.
4. " acrid vegetables [Nettle, etc.].
j. Effects of poison in wounds.
1. From bites of insects, reptiles, and other animals.
2. From septic infection.
3. " poisoned weapons.

EXTERNAL AUDITORY CANAL.

I. *Abnormalities.*
a. Arrested development.
1. Absence of external auditory canal.
2. Atresia congenita (membranosa, ossea).
3. Abnormal width.
4. Congenital contraction.
b. Excessive development.
1. Thickening of cutaneous lining. [*Vide* New Growths.]
c. Irregular development.
1. Meatus bivius.

II. *Hyperæmia.*
III. *Periostitis.*
IV. *Circumscribed Inflammation.*
V. *Diffuse Inflammation* (acute, chronic).
VI. *Croupous Inflammation.*
VII. *Gangrenous Inflammation.*
VIII. *Desquamative Inflammation.*
IX. *Extravasative Inflammation.*
X. *Skin Diseases.*
a. Eczema.
b. Erysipelas.
c. Erythema.
d. Herpes.
e. Pemphigus.
f. Ulcer, hæmorrhage.
XI. *Anomalies of Secretion.*
a. Cerumen (deficiency, excess), Cretaceous Bodies, Otomycosis (Aspergillus Nigricans, A. Flavescens, A. Fumigatus, Graphium Penicilloides, Aschophora Elegans, Trichothecium, Mucor Mucedo seu Fuscus, Otomyces Hageni, O. Purpureus).
b. Seborrhœa.
c. Desquamation, laminated epithelial plug.
XII. *Stricture*—Stenosis.
XIII. *Adhesion of Walls*—Bands.
XIV. *Collapse of Cartilaginous Portion.*
XV. *Caries and Necrosis*—Communicating sinus from parotid gland, attic of tympanum, or adjacent pneumatic cells.
XVI. *Granulation*—Hæmorrhage.
XVII. *New Growths.*
a. Enchondroma.
b. Epithelioma.
c. Exostosis (pedunculated, broad-based).
d. Hæmatoma.
e. Hyperostosis.
f. Milium.
g. Thickening of cutaneous lining of canal. [*Vide Abnormalities.*]
h. Polypus.
i. Sarcoma.
j. Sebaceous tumor.
XVIII. *Wounds and Injuries.*
a. Lacerated wound.

b. Contused wound.
c. Incised wound.
d. Punctured wound.
e. Shot wound.
f. Fracture. [*Vide Wounds and Injuries of Auricle.*]

XIX. *Foreign Bodies.*
a. Animate objects.
b. Inanimate objects.

XX. *Ingrowing Hairs from Tragus and Canal pressing upon the Membrana Tympani.*

MEMBRANA TYMPANI.

I. *Abnormalities.*
a. Arrested development.
1. Absence of manubrium mallei.
2. Absence of membrana tympani.
b. Excessive development.
c. Irregular development.

II. *Trophic Changes.*
a. Atrophy.
b. Calcareous degeneration.
c. Opacity—Fibrous hypertrophy (?).
d. Cicatricial regeneration [manometric].

III. *Myringitis, Simplex.*
a. Inflammation of pars flaccida (acute, chronic).
b. Inflammation of pars vibrans (acute, chronic).

IV. *Myringitis, Desquamative.*

V. *Myringitis, Extravasative* [Hæmatoma of drum-head].

VI. *Abscess.*

VII. *Chronic Ulcer*—Hæmorrhage.

VIII. *Wounds and Injuries.*
a. Rupture.
1. From boxing auricle.
2. From pulling auricle.
3. From falling on auricle.
4. From syringing canal.
5. From condensing air in canal or Eustachian tube.
6. From rarefying air in canal or Eustachian tube.
7. From fracture of base of skull.
b. Perforation by puncture, or incision, with foreign body, or instruments.
c. Abrasion from impacted cerumen, foreign body, or instruments.
d. Concussion from impacted cerumen, foreign body, or instruments.
e. Straining from pulling auricle.
f. Effects of cold from bathing, diving, or syringing canal.

IX. *Skin Diseases.*
a. Eczema.
b. Erysipelas.
c. Erythema.

X. *New Growths.*
a. Cholesteatoma.
b. Epithelioma.
c. Syphilide.
d. Tubercle.
e. Vascular tumor.

XI. *Foreign Bodies.*
a. Animate objects.
b. Inanimate objects.

MIDDLE EAR TRACT—TYMPANUM—ATRIUM, ATTIC, AND ANTRUM.

I. *Abnormalities.*
a. Arrested development.
1. Absence of membrana tympani.
2. Absence of part or all of ossicles.
3. Absence of tympanum.
4. Absence of labyrinthine fenestræ.
5. Absence of eminentia pyramidalis.
b. Excessive development.
1. Fusion of ossicles.
2. Overgrowth of ossicles.
3. Superfluous ossicles.
c. Irregular development (?).

II. *Hæmorrhage*—Vicarious menstruation.

III. *Acute Non-suppurative Otitis Media.*

IV. *Mucous or Muco-serous Catarrhal Otitis Media* (acute, subacute, chronic—trophic).

V. *Suppurative Otitis Media* (acute, subacute, chronic).

VI. *Croupous, Diphtheritic, and Desquamative Otitis Media.*

VII. *Caseous Otitis Media.*

VIII. *Chronic Dry and Adhesive Catarrhal Otitis Media.*

IX. *Sclerosis.*

X. *Caries of Tympanum.*

XI. *Caries of Ossicles.*

XII. *Fracture and Dislocation of Ossicles.*

XIII. *Syphilitic Inflammation of Tympanum* (secondary, tertiary).

XIV. *Wounds and Injuries.*
a. Through Eustachian tube.
b. Through membrana tympani.
c. By fracture of base of skull.

XV. *Embolism in Mucous Membrane.*

XVI. *New Growths.*
a. Cholesteatoma.
b. Cyst.
c. Epithelioma.
d. Exostosis of tympanum.
e. Exostosis of ossicles.
f. Hyperostosis of tympanum.
g. Hyperostosis of ossicles.
h. Osteosarcoma.
i. Polypus { mucous } muco-fibrous. { fibrous / mucoid } myxo-fibrous.
j. Tubercle.

XVII. *Foreign Bodies.*
a. Animate objects.
b. Inanimate objects.

COMPLICATIONS OF DISEASE OF MIDDLE EAR TRACT.

I. *Periostitis of Cortex of* [*osseous*] *Ext. Auditory Canal.*

II. *Disease of Mastoid Process.*
a. Periostitis of cortex of mastoid process.
b. Inflammation of pneumatic cells of mastoid process (catarrhal, purulent, cheesy — acute,

chronic). [All inflammations of the tympanum are *apt* to involve, in secondary inflammation, the pneumatic cells of the mastoid process, and *vice versa*.]

c. Caries and necrosis of mastoid process.

d. New growths of mastoid process.

a. Cholesteatoma.

b. Epithelioma.

c. Exostosis.

d. Hyperostosis.

e. Polypus. [*Vide* Polypus of Middle Ear Tract.]

III. *Circumauricular Abscess.*

IV. *Facial Paralysis* [Bell's Palsy].

V. *Fracture of Base of Skull.*

VI. *Pachymeningitis.*

VII. *Leptomeningitis.*

VIII. *Cerebral Abscess.*

IX. *Thrombosis.*

X. *Embolism.*

XI. *Phlebitis.*

XII. *Pyæmia.*

XIII. *Constitutional Disease.*

a. Rheumatism.

b. Phthisis.

c. Rhachitis.

d. Syphilis.

e. Exanthemata.

1. Scarlet fever.
2. Typhus fever.
3. Typhoid fever.
4. Measles.
5. Variola.
6. Varioloid, etc.

f. Whooping-cough.

g. Diphtheria.

h. Bright's disease.

i. Diabetes.

j. Genito-sexual disturbance.

1. Puberty.
2. Pregnancy.
3. Menopause.
4. Masturbation.
5. Excessive venery, etc.

k. Abuse of systemic materia medica.

XIV. *Oral Irritation or Disease.*

XV. *Orbital Irritation or Disease.*

XVI. *Nasal Irritation or Disease.*

XVII. *Pharyngeal Irritation or Disease.*

XVIII. *Mumps.*

XIX. *Disease of External Ear.*

XX. *Disease of Internal Ear.*

MASTOID PROCESS.

FAILURE OF COCAINE HYDROCHLORATE TO PRODUCE ANÆSTHESIA.

By HENRY J. GARRIGUES, M. D.

Recently I had to perform an operation in order to restore to an available condition a vulva which, in a perineorrhaphy performed by another surgeon, had been closed up to such an extent as barely to admit the index-finger and not the organ to which it physiologically is destined to give passage.

The patient was a married woman, thirty-seven years of age. I had to cut fully one inch backward from the artificial posterior commissure, after which I united the skin with the mucous membrane by sutures.

Since here was only a thin layer of skin and mucous membrane to be cut, both surfaces of which were easily accessible, it seemed to be a case peculiarly well fitted for local anæsthetization. I began by painting both surfaces with a four-per-cent. solution of hydrochlorate of cocaine. When two grains of the salt had been used in this way and there was not the slightest diminution in the sensitiveness of the skin, I injected a quarter of a grain hypodermically into the tissue to be divided, and continued soaking the skin and the mucous membrane. About seven minutes after the first hypodermic injection I repeated it, introducing the needle from the posterior commissure all the way back as far as the tissues were to be divided. In spite of the previous injection, this caused as much pain as if nothing had been done before to produce anæsthesia.

This second time, likewise, a quarter of a grain of the salt was injected slowly, while withdrawing the needle, over the whole tract with which it came in contact. Finally I bathed again the two surfaces until I had used in all five grains of hydrochlorate of cocaine, one half grain of which had been injected hypodermically. This application of a four-per-cent. solution had then been kept up for twenty-five minutes.

In spite of this thorough and protracted application of

a comparatively strong solution of cocaine, the sensibility was not lessened the least, so far as the complaints and screams of the patient could be used as a measure of her pain.

The price of the cocaine used was two dollars.

Ernst Fränkel, of Breslau ("Centralblatt für Gynäkologie," December 6, 1884, vol. viii, p. 778), has likewise found the common solutions ineffective on the vagina, and recommends a twenty-per-cent. alcoholic solution; but, when we take into consideration the high price of the drug, so expensive a solution can only be used in exceptional cases. The patients, unless money be no object at all, will prefer to stand the pain or to be etherized.

NEW YORK, SATURDAY, AUGUST 29, 1885.

THE SPECIAL MEETING OF THE CONGRESS COMMITTEE.

As we have already notified our readers, the American Medical Association's new Committee on the International Medical Congress is to hold a special meeting in New York on Thursday of next week. Regardless of what action may be taken, the mere fact that such an extraordinary meeting is to be held, after the committee had concluded its work of demolition and adjourned until next spring, is a gratifying proof that the spontaneous and widespread dissent that has been expressed by the better portion of the profession from the absurd course laid out by the American Medical Association has not failed to produce an effect. It is the most decided and unmistakable of numerous indications that a change has come over the spirit of the New Orleans agitators' dream.

It is to be presumed that the meeting will undertake little else than the repair of damages—that is, the appointing of others to take the places of the distinguished men who have declined to take part in the present organization. That any such action will fail of its purpose seems to us unquestionable. We do not doubt, indeed, that men enough can be found who will be willing and even glad to hold official positions in a gathering that will be international only in name. But, allowing that the committee made the best choice it could have made at Chicago, any selections that it makes now must necessarily be of inferior men, and it is doubtful even if men a grade below those first chosen would be willing to figure before the world as the recipients of appointments that had gone begging. It can scarcely be doubted, therefore, that the corps of appointees will be largely inferior to the remnants left by the recent defections. Far from having been mended, matters will then have been made worse; but, if this is to be the result, it is best that it should come promptly, that the remedy may follow the more speedily.

Besides patching up the organization, the committee may try to palm off upon the country something having the semblance of a compromise as to the qualifications of those who are to be allowed to take part in the Congress non-officially, but it will be surprising if anything remotely resembling decency is put forward in this direction—in fact, nothing of the sort is possible except a complete reversal of the tinkering that the organization has undergone.

By this time the plotters who are behind the committee undoubtedly understand that it will profit them nothing to pursue the petty scheme of inducing Dr. Shoemaker to play the part of a scapegoat and resign, although it is but a few weeks since they professed in private to count confidently upon that sop to Cerberus.

There is one plain course open to the committee, and one only, by which it may save its own credit and do the only thing possible to rescue the Congress from destruction—and that is, to rescind everything it has thus far done, and to resolve to ask the American Medical Association to discharge it. This would practically restore the old organization, and, although it would come rather late, might result in reviving the bright prospects of the Washington Congress as they existed six months ago.

THE POSTURES OF SCHOOL CHILDREN.

An English surgeon, Mr. Noble Smith, who is connected with a children's hospital, and who appears to have something to do officially with the Board Schools of London, lately read a very important paper before the Medical Officers of Schools Association, which is published in the "Medical Times and Gazette." The title of Mr. Smith's paper is "Postures in School, and their Influence upon the Figure." He deals, however, not only with the influence of strained and unnatural postures upon the figure, but also with their effect upon health and strength in other ways, and with a number of collateral matters relating to school hygiene, such as the management of the light used for reading and writing, etc.

In one instance he measured the distance between the pupil's eyes and the copy-book, and found it to be only two inches and a half. It does not appear that this was the result of nearsightedness on the part of the pupil, but of faulty construction of the desk, which was too low and removed too far from the pupil's body. From these and various other defects in the arrangement of the chair and desk, and from certain enforced attitudes which are supposed to favor an elegant handwriting, roundness of the back and lateral curvatures of the spine were found to be frequent results. The author calls attention to the deleterious effects of all this upon the individual, especially as regards the breathing capacity. Girls are most affected, as they are held to a more rigid observance of postures that are deemed decorous, while at the same time they are in great measure denied the counterbalancing effects of free and unrestrained play, their diversion being too often restricted to a prim and stately walk in couples.

Of late years, much attention has been given to these matters in the United States, and the result has been a very decided improvement, but it is very much to be feared that we are not yet altogether free from the evils that are so vividly depicted by Mr. Smith as occurring among the school children of London.

MINOR PARAGRAPHS.

AN ACCIDENT IN A PARIS HOSPITAL.

A deplorable mistake was lately made at the St. Louis Hospital, in Paris, which resulted in the death of two patients. According to the account given in the "Progrès médical," a preparation popularly termed *eau-de-vie allemande*, which is a compound tincture of jalap, was ordered by the physician, but the pupil on duty in the pharmacy put up *gouttes amères de Beaumé* instead, the latter being a mixture containing ignatia. The pupil is described as having been wild with despair when he learned of the fatal consequences of his error, and another account states that it was with difficulty that he was prevented from committing suicide. "Progrès médical" is probably correct in its suggestion that the "reactionary" newspapers would have been loud in their outcries if the affair had happened in one of the hospitals where lay officials are employed.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 25, 1885:

DISEASES.	Week ending Aug. 18.		Week ending Aug. 25.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	1	0
Typhoid fever	23	6	29	10
Scarlet fever	25	4	14	4
Cerebro-spinal meningitis	1	1	3	1
Measles	31	3	12	6
Diphtheria	30	16	31	17
Yellow fever	1	0	0	0

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, August 12th. *Three Rivers, Canada.*—For the week ending August 8th: Free from epidemic diseases. The consul reports that there is no small-pox below Montreal, where there has been a total of 120 deaths up to the end of the second week in August. *Havana, Cuba.*—For the week ending July 30th: 25 cases of yellow fever and 3 deaths. *Cardenas, Cuba.*—For the two weeks ending August 8th: Free from cholera and yellow fever. *Matanzas, Cuba.*—For the week ending August 5th: No cholera or yellow fever. *Cienfuegos, Cuba.*—For the week ending July 15th: No cholera or yellow fever. *St. Thomas, W. I.*—For the week ending July 25th: Intestinal catarrh and acute diarrhœa prevalent, but in a mild form. Very few fatal cases. *Nassau, N. P.*—For the week ending August 1st: No epidemic diseases. *Curaçoa, W. I.*—For the week ending August 15th: In good sanitary condition. *Guaymas, Mexico.*—For the month of July: City and district in good sanitary condition. *Vera Cruz, Mexico.*—For the month of July: 84 deaths from yellow fever. The disease is said to be epidemic. *Acapulco, Mexico.*—For the week ending July 26th: Free from epidemic diseases. *Callao, Peru.*—For the week ending July 18th: Yellow fever has disappeared, but small-pox prevails among the lower classes. *La Guayra, Venezuela.*—For the week ending August 8th: In good sanitary condition. *London, England.*—For the week ending August 8th: Deaths from diarrhœa and dysentery, 309; from cholera or choleraic diarrhœa, 11, and from small-pox, 14, including 9 of London residents who died from the disease outside the registration district. On August 8th there were 518 cases of small-pox in the London hospitals, being 96 less than in the previous week. The admissions during the week were 43, there having been 69 during the preceding week. *Bristol, England.*—For the week ending August 8th: 1 death from cholera. *Paris, France.*—For the two weeks ending August 8th: 61 cases and 3 deaths from small-pox, 213 cases and 36 deaths from typhoid fever. *Bordeaux, France.*—For the month of July: 4 deaths from small-pox. *Marseilles, France.*—By cable, August 25th: Deaths from cholera average 55 daily. *Toulon, France.*—By cable, August 25th: 25 deaths from cholera on the day previous. *Barcelona, Spain.*—For the week ending July 31st: 1 death

from small-pox; 36 deaths from unclassified contagious diseases; gastric and intestinal catarrh prevalent. *Antwerp, Belgium.*—For the two weeks ending August 1st: 26 cases and 5 deaths from small-pox. *Cadiz, Spain.*—For the week ending August 8th: Free from epidemic diseases. *Valencia, Spain.*—For the two weeks ending August 2d: 785 cases of cholera and 369 deaths. *Genoa, Italy.*—For the week ending August 2d: 1 death from small-pox. *Venice, Italy.*—For the two weeks ending August 1st: 20 deaths from small-pox. *Trieste, Austria.*—For the week ending August 1st: 6 cases of small-pox and 2 deaths. *Prague, Austria.*—For the week ending August 6th: 2 deaths from small-pox. *St. Petersburg, Russia.*—For the week ending July 25th: 6 deaths from small-pox. *Warsaw, Russia.*—For the two weeks ending August 1st: 9 deaths from small-pox. *Calcutta, India.*—For the week ending July 4th: 16 deaths from cholera. *Bombay, India.*—For the week ending June 30th: 6 deaths from cholera as against 2 during the previous week.

The Cholera in Spain.—According to information received by the "Gazette hebdomadaire de med. et de chir.," there had been, up to July 31st, 114,714 cases and 34,003 deaths. In Madrid the number of cases was 4,058, with 1,353 deaths. The number of infected towns was upward of 380.

Typhoid Fever is reported as being prevalent in the Lunatic Asylum at Morris Plains, N. J., thirteen cases having already occurred, with but one death. The outbreak of the disease is attributed to defective sewerage.

Scarlet Fever has, it is alleged, been conveyed from an infected family to others in Jamesport, Long Island, by the total disregard of instructions from the Board of Health, who ordered the father to quarantine the family, the man contending that the disease was not contagious, and permitting members of his family to go and come at will. He is likely to pay the penalty of his disobedience and ignorance.

The International Medical Congress.—We learn that Dr. Delavan Bloodgood, Medical Director in the navy, has declined to hold the position to which he was appointed by the new committee. As will be seen by his letter, printed in another column, Dr. Alfred L. Carroll, the secretary of the New York State Board of Health, has also pursued the same course. Dr. Henry D. Noyes, of New York, has sent the following letter to Dr. John V. Shoemaker, the secretary of the committee: "I beg to acknowledge your favor of the 19th ult., informing me of my appointment as First Vice-President of the Ophthalmological Section of the Ninth International Medical Congress by the committee which met at Chicago. This position I can not accept, because by so doing I should assent to the action of the American Medical Association, which has thrust into the International Medical Congress a controverted subject with which the Congress has no concern, and has determined to exclude from all official position the medical men whose convictions in this regard it disapproves of. I refuse to admit that the composition of the International Medical Congress should be in any way determined by the controverted points of the Code of Ethics of the American Medical Association. I also refuse to join in treating with neglect or disrespect honorable and eminent physicians who do not accept all the restrictions of that code about medical consultations. The right of the American Medical Association to take this course can, I think, be successfully challenged, but, for my own decision, it is enough that I can not concur with it, and that I feel sure that its pursuance will prove most hurtful to the Congress, in whose welfare, as you know, I have taken a deep and active interest. For the courtesy of the committee in tendering me this honor I beg you to express my thanks."

The British Medical Association.—A correspondent informs us that Dr. H. P. C. Wilson, of Baltimore, has been elected a member of the association.

Dr. Oliver Wendell Holmes will reach his seventy-sixth birthday to-day.

The Medical Society of Virginia will hold its annual meeting at Alleghany Springs on the evening of Tuesday, September 15th. The session promises to be one of unusual interest.

The Mississippi Valley Medical Association will meet at Evansville, Ind., on Tuesday, Wednesday, and Thursday, September 8th, 9th, and 10th. Railroad and hotel rates will be reduced for the occasion. Full particulars can be obtained of Dr. A. M. Owen, Evansville, Ind.

The Death of Prof. Berger, of Breslau, who, although young, was distinguished as a neuro-pathologist, is announced in the "Revue de médecine."

The Death of Prof. Aeby is also announced by the same journal. He was well known as an anatomist.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 16, 1885, to August 22, 1885:*

Wolverton, W. D., Major and Surgeon. Granted leave of absence for twenty days. (Washington Barracks, D. C.) S. O. 171, Department of the East, August 14, 1885.

Maus, L. M., Captain and Assistant Surgeon. In addition to his other duties, assigned to duty as attending surgeon of the Department Rifle Camp. S. O. 83, Department of Dakota, August 3, 1885.

Black, C. S., First Lieutenant and Assistant Surgeon. Upon return of troops F and L, Third Cavalry, to Fort Davis, Texas, to rejoin his proper station, Fort Clark, Texas. S. O. 98, Department of Texas, August 13, 1885.

McCaw, W. D., First Lieutenant and Assistant Surgeon. Having reported back at these headquarters from detached service, ordered to rejoin his proper station, Fort Lyon, Colorado. S. O. 122, Department of the Missouri, August 17, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the two weeks ending August 22, 1885.*

Beyer, H. G., Passed Assistant Surgeon. To attend meeting of the American Association for Advancement of Sciences, at Ann Arbor, Michigan, and at conclusion of meeting to resume duty at the Smithsonian Institution.

Boyd, John C., Passed Assistant Surgeon. Ordered from Navy Yard, Washington, D. C., to special duty at Bureau of Medicine and Surgery, Washington, Navy Department.

Drennan, M. C., Surgeon. Assigned to temporary duty at Annapolis, Md., as member of board for physical examination of candidates for admission to U. S. Naval Academy.

Lippincott, J. C., Passed Assistant Surgeon. Ordered to Navy Yard, Washington, D. C., as relief of Passed Assistant Surgeon Boyd.

Owens, Thomas, Assistant Surgeon. Relieved from special duty at Bureau of Medicine and Surgery, Navy Department, and waiting orders.

Sayre, J. S., Assistant Surgeon. Ordered from United States Receiving-Ship Independence to Naval Hospital, Mare Island, California.

Simon, Wm. J., Surgeon. Assigned to temporary duty at Annapolis, Md., as member of board for physical examination of candidates for admission to U. S. Naval Academy.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the week ending August 22, 1885.*

Bailhache, P. H., Surgeon. Granted thirty days leave of absence. August 15, 1885. Chairman of board to examine candidates for appointment as cadet in the Revenue-Marine Service. August 19, 1885.

Irwin, Fairfax, Passed Assistant Surgeon. Recorder of board. August 19, 1885.

Society Meetings for the Coming Week:

Tuesday, *September 1st:* Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Franklin and Niagara (Lockport), N. Y.; Hudson County, N. J., Medical Society (Jersey City); Androscoggin County, Me., Medical Association (Lewiston).

Wednesday, *September 2d:* Medical Society of the County of Richmond, N. Y. (Stapleton).

Thursday, *September 3d:* New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.; Obstetrical Society of Philadelphia.

Friday, *September 4th:* Practitioners' Society of New York (private).

Saturday, *September 5th:* Clinical Society of the New York Post-Graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Letters to the Editor.

THE DISINFECTION OF RAGS.

Baltimore, *August 23, 1885.*

To the Editor of the New York Medical Journal:

Sir: I am glad to learn from the letter of Mr. Augustine Smith, published in the "New York Medical Journal" of August 8th, that the paper-makers do not object to the disinfection of rags from infected ports, and are even willing, "out of deference to public opinion," to have their importation from such ports entirely prohibited.

I for one should not be inclined to insist upon the disinfection of rags shipped from healthy ports if we could be sure that they had not been collected in infected localities. Here is the great difficulty with which health officers have to contend. It is evidently impossible in many instances to ascertain exactly where the rags have been collected. For example, if an English ship, sailing from Southampton or Liverpool, should bring a cargo of rags to New York, would any one suspect the possibility that these rags might have been collected in Spain? Yet this is not simply a possibility, but seems to be quite a probable event in view of the recent order of the Local Government Board, dated June 23, 1885. I quote from this order Articles II and III:

"Article II. From and after the date of this order, and until the first day of November, 1885, no rags from Spain shall be delivered overside, *except for the purpose of export* (italics are mine), nor landed in any port or place in England or Wales."

"Art. III. If any rags are delivered overside or landed in contravention of this order, they shall, *unless forthwith exported*, be destroyed by the person having control over the same, with such precautions as may be directed by the medical officer of health of the sanitary authority within whose jurisdiction or district the same may be found."

Comment is scarcely necessary; evidently a merchant receiving a cargo of rags from Spain has but one way to save his property from destruction, under the order of the Local Government Board, viz., to "forthwith" export the rags to the United States, or some other country willing to receive them.

Those who have opposed the disinfection of rags have claimed that there is no case on record in which cholera has been transmitted by means of rags. Even if this were true, the evidence that is on record with reference to the communication of the disease to laundresses by means of the soiled linen of the sick would be a sufficient reason for excluding rags from infected ports, unless disinfected in a satisfactory manner. But there is a case on record which seems to be well authenticated. I quote from a letter received a few days since from Dr. Sonderegger, president of the Swiss *Aerzte Commission*, and delegate from Switzerland to the International Sanitary Conference of Rome:

"The fact relating to rags was observed and described by Prof. Biermer (living now in Breslau as Professor of Practical Medicine), and by Dr. Zehnder, vice-director of the board of health (Sanitätsrath), who were both most active at the time of cholera at Zurich in 1867: July, August, September, October, number of patients 684; number of deaths 65·9 per cent.

"Kriegstetten is a small village in the canton of Solothurm, at eighty to one hundred kilometres distance from Zurich, and not connected with this town either by water (lake, river, marsh) or by trade and industrial commerce. There is a paper-mill at Kriegstetten, and a work-woman, who had to tear the rags, was suddenly taken with cholera and died the following day. The following days sixteen more work-women (all occupied in tearing the rags) were taken sick: of these, eleven died. A careful examination showed that all of these rags went from Zurich and from cholera-houses; therefore the whole mass of rags was disinfected by boiling. After this no case of cholera occurred. The large establishment of the paper-mill, as well as the village, remained free. I mentioned the fact in a little address to the Swiss people, which I have the honor to send you,* and nobody doubted the fact or made any opposition. The fact was known everywhere in Switzerland."

George M. Sternberg.

THE INTERNATIONAL MEDICAL CONGRESS.

Albany, *August 21, 1885.*

To the Editor of the New York Medical Journal:

Sir: Soon after the meeting at Chicago of the new committee to rearrange the International Medical Congress I saw my name mentioned in a reported list of proposed officers of sections. As this was not an authenticated publication, I did not feel warranted in taking action until I should receive the customary official notification of appointment. Finding, however, that none of those named in the printed report appear to have been otherwise notified, and being unwilling to remain in an attitude of even seeming ambiguity, I beg to say that I have no intention of holding any position in connection with the proposed scheme. I am, sir,

Faithfully yours,

Alfred Ludlow Carroll, M. D.,
Fellow State Medical Association.

* This "little address" is an admirable sanitary tract, giving practical directions relating to disinfection, etc. G. M. S.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of June 18, 1885.

The President, Dr. A. Jacobi, in the Chair.

The Operation for Lacerated Perinæum.—Dr. H. W. Mitchell read a paper in which he described his method of repairing the lacerated perinæum, which, he said, was essentially the method practiced about as long ago as 1850 by Dr. Isaac E. Taylor, and which had been practiced by Dr. Thomas and others. He thought to repair the perinæum was a simple procedure—one which any surgeon of ordinary skill and knowledge of the parts could carry out. The lacerated parts being held apart by two assistants, the surgeon introduced his left index-finger into the rectum, and with curved scissors pared off the mucous membrane of either side down to the median line, taking care not to go up too high on the sides, which would be to leave a pocket between the rectum and vagina after the sutures had been passed. The parts were now ready for the passage of sutures. These he introduced by the small sized curved needle, commencing below, and passing them sufficiently deep to give a firm support. The number passed was usually three or four. He used silver wire, threaded directly on the needle, thus dispensing with the ordinary clumsy method of first passing a silk suture, and by this jerking a wire through. He then passed some superficial silk sutures and approximated the edges of the skin. Having made the bowels move freely previous to the operation, he kept them confined about six days afterward. Cleanliness was sufficient antiseptic precaution; ont of forty cases, the histories of all of which he read, carbolic-acid solution was used in only five, and in the others no so-called antiseptics were employed. In all of the forty cases there was union by first intention; the wires were usually taken out on the sixth or seventh day; in a number of the cases a laceration of the cervix uteri was repaired at the same time. None of the operations were primary.

Dr. A. C. Post said that, the author's cases having been so eminently successful, no exception could be taken to either the discarding of antiseptics or the details of the operation. He thought, however, there was an advantage in keeping the bowels free after the operation, and he thought this plan was now coming into general practice.

Dr. Malcolm McLean could not understand how the author had found drawing the silver wire through by means of the silk loop a disadvantage when all other operators had found the loop an advantage. He also thought the curved needle had generally been discarded because it was liable to turn or to break; the modern method of lifting the parts into line and passing the straight needle he thought much better. Nor could he understand how it happened that Dr. Mitchell's patients escaped pain after the operation, which others had always found to be so troublesome.

Contagious Conjunctivitis.—Dr. Joseph A. Andrews read a paper on this subject. It will be published in full hereafter.

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of February 26, 1885.

The President, Dr. B. F. Westbrook, in the Chair;

Dr. A. H. P. Leuf, Secretary.

Pulmonary Gangrene.—Dr. Eliza M. Mosher read a paper giving a history of a case of this sort, with remarks. [See p. 233.]

Demonstrations of an Easy Method for the Estimation of Urea and Sugar in the Urine was the title of a paper read Dr. W. M. Hutchinson.

Cæsarean Section.—Dr. Charles Jewett read a paper giving the history of a case, with remarks. [See p. 231.]

Intra-ocular Melano-sarcoma.—Dr. Arthur Mathewson related the case of a patient, fifty-nine years old, who had first been examined by him November 28, 1882, when a large detacht ment of the retina, in the lower part of the fundus of the right eye, was discovered with the ophthalmoscope. The vision of the eye was totally lost in the course of a few months, but there was no pain or inflammatory symptoms till the autumn of 1884, when the other eye became red and painful, with great increase of tension. The crystalline lens had become opaque so that nothing of the fundus could be seen. Other means of relief from the torturing pain having failed, the eye was enucleated October 30, 1884, when a large melanotic mass was found occupying three fourths of the vitreous chamber, and extending back through the sclera about the optic nerve. Microscopic examination showed the growth to be a melano-sarcoma. The point of chief interest in this case was the fact that there was nothing in the appearance at the first ophthalmoscopic examination to distinguish it from an ordinary detachment of the retina from other causes, and nothing to indicate its dangerous character. The lesson to be drawn from it was, always to be on the lookout for morbid growths behind the retina as a possible cause of its detachment, and to enucleate early where there seemed to be just ground for this suspicion. In this case, as in others formerly presented by him to the society, sooner or later some of the abdominal viscera would probably become the seat of melanotic growths. As yet there was no appearance of the growth in the orbital tissues.

A Fœtus of Five Months and a Half, as was estimated, was shown by Dr. E. H. Bartley, who said that it had lived quite thirty-two hours after its birth.

Urethral Stricture, with Complications.—Dr. C. N. D. Jones read a paper embracing the history of the case, with remarks. [See p. 235.]

Cancer of the Breast.—Dr. George Waokerhagen related the case of a woman, forty-five years old, who had been married twenty-six years and had never been pregnant. She ceased to menstrnate at the age of forty-three. Six months ago she first noticed a small lump in the left breast. It enlarged very slowly, and she did not complain of pain until about six days before the operation; it was then of a burning and shooting character. The breast was removed on the 10th of January, together with all the axillary glands, although the latter were not diseased. Strict antiseptic precautions were observed, and the patient made a good recovery. Microscopical examination showed the tumor to be a typical carcinoma, with thick alveolar walls and small alveoli containing epithelial cells.

Abdominal Cancer, with Perforation of the Stomach.—Dr. W. C. Burke, Jr., of South Norwalk, Conn., read the history of the case. [The author reserves it for future publication.]

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of June 16, 1885.

The President, Dr. J. A. McCorkle, in the Chair;

Dr. Z. T. Emery, Secretary.

The Salicylic-Acid Treatment of the Intestinal Catarrh of Infancy.—Dr. W. A. Northridge read a paper with this title. [See p. 229.]

Dr. E. H. Bartley said that he had had some little experience in the salicylic-acid treatment of the diseases of children. He had begun this treatment in 1880, taking the suggestion from a paper read before this society by Dr. Hutchins. Dr. Hutchins had used the same treatment recommended by the author of the paper just read, and had reported very flattering results. He, however, recommended it only in certain cases—if the speaker's memory served him, in cases of watery diarrhœa, in cholera infantum, so called; and in those cases he obtained very excellent results. The speaker had begun the use of it, hoping to find something that would check the large number of cases that he was called upon to treat, and he must say that he had been very much disappointed in the drug. Since then he had used it more or less every summer, but he selected the cases. He thought it a valuable remedy, but he would not laud it so highly as the author of the paper had. In the histories that had been reported we must consider one thing which was very favorable to the drug, and that was that these patients had been sent from an over-heated, over-crowded, and filthy tenement-house region, as a rule. They were the children of poor people who could not afford even fresh air at home, and they were sent to the island for the purpose of securing fresh air. All of them, with one exception, if he remembered rightly, were put upon the salicylic treatment on reaching the island. We should naturally expect an improvement, with any treatment or no treatment, in children taken from a heated, over-crowded part of the city and brought to Coney Island, where they got a free supply of fresh cool air. That, of course, was favorable to the drug, and made the author's statistics look a little brighter than they would look if he had had to treat children in Front, Water, Hicks, Columbia, or Van Brunt street. Histories from those streets would show a much smaller number of cures. Still, as he had said before, with selected cases there was a great deal of efficiency in salicylic acid. These selected cases were those of true fermentative diarrhœa—a point that he had laid some stress upon in a paper read before the society a year ago. There were some cases that began as a true fermentation in the undigested food of the lower canal, giving rise to intestinal catarrh, afterward extending either to the stomach, producing gastro-enteric catarrh, or extending downward and becoming a colitis. In such cases salicylic acid would act beneficially. He was not sure but it would act fully as well, if not better, if administered in the form of salicylic acid instead of this form of salicylate of calcium.

The author had made the remark that the effect was due principally to the salicylic acid. If that was true, of course it would be quite as well to use salicylic acid. A part of the effect was due to the anti-fermentative effect of salicylic acid, and part to the astringent effect of salicylate of calcium. He thought it was a little unfortunate that the author had not attempted to give us a little more of his impression as to whether these cases were of this fermentative character. Of course, his means of observation in that respect had not been what they would be in treating a case from its inception. He took the case well established, and did not know much of the previous history, except from a very brief statement sent with the patient; but the speaker thought it was stretching the thing a little, to say the least, to recommend the method as a wholesale treatment in all cases of summer diarrhœa. Instead of salicylic acid he had found benzoate of sodium or of ammonium to be equally efficient. To check the green stools, accompanied by undigested food and the free fatty acids, he had found the benzoate of sodium or benzoate of ammonium, in doses of from one to two grains, to answer the purpose very well. We all knew the benefit of calomel in these cases. It prevented the secondary fermentation, and had a very soothing effect upon the mucous membrane. The effect upon the nervous system was greater, perhaps, from calomel than from salicylic acid.

In regard to the use of opium, he thought he had had the best success with it in the treatment of watery diarrhœas; but in nearly all such cases, or in a great many, he had used one of the anti-fermentatives, and had settled down upon the benzoates.

Dr. Walter B. Chase said that, without questioning the accuracy of the author's observations regarding the cases which were under treatment at the Sea-side Home, it seemed to him that, as had been suggested by the last speaker, the value of any given course of treatment of a case of entero-colitis or allied summer diseases of children would be determined, not principally by the effect of treatment away from home, but by the effect of treatment at home; and so the value of statistics which were made at the sea-side, away from home, was somewhat uncertain, because we were unable to estimate the value of the hygienic surroundings and the change of atmosphere. This was a very large question to discuss, and he did not purpose to occupy more than a moment. He was coming to believe that, apart from hygienic surroundings, very much depended upon whether these little ones who were fed artificially were properly fed. He believed it was the common experience that at home, or at the sea-side, or in the mountains, the question of digestion, both gastric and intestinal, was the principal factor in the safety of the patient and the time of recovery. No doubt one great trouble in the treatment of these cases had been due to the fact that these little ones had been overfed, which added to the depressing effect of heat and of fermentative action in the alimentary canal. The feeding in many cases had been of an improper kind and at improper intervals. If these children could be fed less, and given some fluid which contained very little nourishment, like barley-water or rice-water, the chances for recovery would be vastly increased. He had had some experience in the use of pancreatic extract in the preparation of milk for artificially fed infants, and was very much interested in it. While he was not prepared to formulate the result of his experience, he believed that, if we could prepare milk in such a manner that when it was acted upon by the juices of the stomach there should be very small coagula or no coagula, by previously digesting the casein, the further process of digestion might go on with safety.

Dr. H. N. Read said that he had had some experience with the treatment described by Dr. Northridge. Dr. Bartley and he had treated a large number of cases of diarrhœa on the plan recommended by Dr. Hutchins some years ago, which was substantially that given by Dr. Northridge, by using a mixture of salicylic acid and chalk. His experience with the remedy coincided with Dr. Bartley's. It was quite useful in some cases, *e.g.*, fermentative diarrhœas, but not at all superior to, or indeed the equal, he thought, of other remedies. The value of the results of the cases mentioned in the report was very much lessened, he thought, by want of comparison and classification. Cases of diarrhœa in infants treated by salicylic acid and chalk in a sea-side sanitarium, with good air and food and wholesome surroundings, and the same cases treated by the same thing in the hot, dirty tenements of the city, would give very different results. Under the former surroundings almost any treatment would give favorable results, while under the latter few plans of treatment would avail. The author had found this remedy equally efficacious in entero-colitis as in the simple diarrhœas. The first case of entero-colitis mentioned in the paper exhibited, if he remembered aright, neither fever nor vomiting, nor was any mention made of bloody stools. It would be extremely interesting to know how the diagnosis of entero-colitis was made under

these circumstances. Entero-colitis, being an acute inflammatory affection of the bowel, was necessarily attended by fever, vomiting, and almost as invariably by bloody and slimy stools. It differed as much from simple diarrhœa as pneumonia did from bronchitis. Its pathology and treatment were essentially different from those of the simple catarrhal diarrhœas. It seemed to him, therefore, that the author claimed too much for the remedy he advocated. While it was useful, undoubtedly, in the treatment of simple diarrhœa, it had no advantages over other remedies.

Dr. TOPHAM said that he could hardly agree with the author as to the use of salicylic acid in the treatment of these diseases. He thought that, instead of their being produced by a germ, it was by the action of undigested food producing irritation. We all knew that this summer diarrhœa was essentially a heat disease, and, if we kept the little ones cool and dieted them properly, they would need no other treatment. He would rather hesitate to put three grains of salicylic acid into a child's stomach when he had it at the sea-side with plenty of fresh air and full control of its diet.

Rhachitis.—Dr. HENRY N. READ read a paper with this title. [See p. 225.]

Dr. BARTLEY said that Dr. Read had spoken of one or two theories in regard to ætiology. Whatever the explanation was, it certainly was due to some form of malnutrition or defective nutrition; and in tracing back the histories of a number of cases he had about come to the conclusion that it was very often due to a long-continued gastro-enteric catarrh. He had risen more especially to call attention to one element in the production of this disease. A man was expected always to speak on his hobby, if he had one, and not go very far outside of it. He was going to speak upon his hobby, and that was milk. He had come to the conclusion that a large number of the cases of gastro-enteric catarrh were originated and kept up by unsuitable milk. He had recently tried an experiment which was very suggestive. It was this: Having visited a farm out in the country, and selected one that he knew was as good a farm as could be made on Long Island, he requested the man to send him milk for the Sheltering Arms Nursery in this city. He was to mark a can "afternoon's milk," so that it would be known when it reached the city. This was taken to the depot, and five or six quarts, whatever was necessary for their use, were to be taken out, placed in a small pail, and delivered at once at the Nursery; so that in the morning, at seven or eight o'clock, the milk of the previous afternoon was delivered at the Nursery without any churning except what it got on the train. The children, small hand-fed babies, were put upon the use of this milk. He noticed immediately an improved condition in all of them, and children that had been dying before, in spite of peptogenic powder and everything else, now began to thrive; and he was satisfied that the trouble that led indirectly or finally to the development of rhachitis was due to improper food and an improper milk. He had come to the practice of prescribing milk for babies as much as medicine. He wanted to know who put up the medicines, and he wanted to know who served the milk. Of course, he had the opportunity of knowing better than most physicians of the good milk-dealers and the poor ones. He could not advertise anybody here; he could only say in general terms that it was always safer to recommend country milk—not somebody's "farm milk," who brought it from his own cows, because those "farms" were, as a rule, little hovels in which as many cows were kept as could endure the place. It was better to take country milk, and take it directly from one of the large dairies. And in this regard he wished strongly to advise every physician to test the milk himself occasionally. An ordinary test-tube would answer for a cream-gauge; and by means of an ordinary urinometer the specific gravity could be determined. In regard to the amount of cream thrown up, it should not be less than ten or twelve per cent. He would not allow a delicate baby to take a milk that threw up less than twelve per cent. There were milks that came directly from the country that did not throw up that, but he would not allow them to be used. The specific gravity of the milk should not be less than 1·030 nor above 1·035, as that indicated thickening. The ordinary milk in its transportation received a great deal of churning, and was sometimes kept four or five days before the baby got it. If it was examined under the microscope, little lumps of butter would be found. The field between the fat globules would have a fine granular appearance. Although it was not sour, it was on the point of souring, and the minute it got into a child's stomach it would be apt to form large curds.

Eclampsia in Early Life was the title of a paper read by Dr. JOSEPH HEALY. [See p. 228.]

Reports on the Progress of Medicine.

ANATOMY AND PHYSIOLOGY.

BY GRÆME M. HAMMOND, M.D.

Distribution of Anæsthesia in Cases of Disease of the Branches and of the Roots of the Brachial Plexus.—Dr. James Ross ("Brain," April, 1884), after making a very exhaustive study of a large number of cases in which the functions of the sensory nerves of the brachial plexus had been destroyed either by disease or by the knife, arrives at the following conclusions: 1. That one of the principal nerve-trunks of the brachial plexus may be completely divided without giving rise to complete anæsthesia in any part of the area of distribution of the sensory branches of the nerve, and that, when complete anæsthesia does occur, the portion of skin affected is very limited, and even the area of skin affected is usually much less than that of the district corresponding to the anatomical distribution of the nerve.

2. That, as a general rule, the anæsthesia caused by division of one or more cutaneous nerves tends to become progressively less in degree and extent with the lapse of time. From this it follows that in division of one or more cutaneous nerves the area of normal sensibility tends to encroach upon the anæsthetic district, so that when one nerve (say the radial) is divided, its area of distribution, when judged by the extent of the anæsthesia, appears to be very small, while, when it is the only one of the three principal nerves of the hand that is spared, its area of distribution, as judged by the extent of the area of normal sensibility, appears to be unusually large.

3. That the extent, degree, and even localization of the anæsthesia caused by the division of any nerve, differ greatly in different cases, without our being able to discover anything in the injury to the nerve or in the external circumstances of the patient which would account for these differences.

4. That the descriptions given by Kraus and by Henle of the anatomical distribution of the digital branches, and especially those derived from the median nerve, correspond more accurately with the results of pathological observations than those usually given in English anatomical works.

On the Connection between Physiological Action and Chemical Constitution.—In relation to this subject Dr. J. Blake ("Journal of Physiology," April, 1884) points out that among the salts of the metallic elements the intensity of their physiological action is connected with the atomic weight of the elements, so that, when the elements are arranged in isomorphous groups, the action of substances in the same isomorphous group is a function of the atomic weight; the greater the atomic weight, the smaller the quantity required to produce the same physiological action. Dr. Blake has tabulated a list of substances

whose physiological action has been investigated, arranged in isomorphous groups, together with their atomic weight. If, in the first or soda group, salts of any of the elements contained therein are injected into the veins in a sufficiently concentrated state to give rise to any well-marked physiological reaction, they kill by arresting the passage of the blood through the lungs, apparently by causing contraction of the pulmonary arteries. When the solution is strong enough, this is so complete that the circulation is immediately arrested and the animal dies, the respiration being stopped by the great venous congestion caused by the blood not escaping from the right side of the heart. Even when injected into the arteries, these substances kill by their action on the lungs, although the quantity is much greater than when injected into the veins.

In the second, or magnesia group, the most marked physiological action of the salts of these elements, when introduced directly into the veins in sufficient quantities, is to suddenly arrest the action of the heart. This takes place in about ten seconds after the salt has been injected. When injected into the arteries they generally arrest respiration before reaching the heart. Even in small quantities their effect on the nervous system is well marked. They give rise to a state resembling catalepsy.

When the salts of the third, or baryta group, are injected in sufficient quantities into the veins, they destroy the irritability of the heart, its pulsation being arrested in diastole. When injected into the arteries, the heart's action is affected in three or four seconds. No appreciable effect is produced on the nervous system, but the most marked results are noticed in their action on the voluntary muscles. With the salts of lime this is shown by a thrill running through the whole of the voluntary muscles, commencing soon after death, and lasting three or four minutes. With the salts of strontia and baryta these movements are much stronger, sufficiently so to move the body half an hour after death.

In the fourth, or aluminum, group the salts of beryllium, alumina, iron, yttria, and cerium have been experimented with. The physiological action of these salts is on the vaso-motor and respiratory centers and on the intrinsic nerves of the heart. Injected into the veins, these salts produce an immediate contraction of the pulmonary arteries. When injected into the arteries, inhibition of the heart's action follows from stimulation of the vagus center.

The salts of the fifth, or platinum group, when injected into the veins, act directly on the intrinsic nerves of the heart, slowing its action with vagus pulsation, the arterial pressure being diminished. When injected into the arteries, the vagus center is immediately affected, the action of the heart being slowed in two or three seconds. The salts of this group retard or render imperfect the coagulation of the blood.

In the sixth group the salts of thoria and cerous oxide have been experimented with. They agree with the alumina group in acting principally on the vagus and vaso-motor centers.

The last of the metallic elements, the action of whose salts has been investigated, is lead. When introduced into the blood, they act similarly to the soda salts in causing contraction of the arteries and the secretion of serum in the bronchial tubes, and an analogous action to the baryta salts, whereby muscular movements continue many minutes after death. They also give rise to contraction of the systemic arteries.

The seventh group contains phosphorus, arsenic, and antimony, and, when introduced directly into the blood, are not followed by any well-marked physiological effects. In poisonous doses they kill either by paralyzing the heart or by their action on the mucous membrane of the lungs, a serous secretion being poured out which prevents the aëration of the blood. The whole of the mucous membrane of the alimentary canal is also acted on.

In the eighth group the salts of sulphur and selenium, when introduced into the arteries, arrest respiration by their action on the nervous system. They do not affect the systemic arteries, but cause secretion from the lung capillaries into the air-passages.

The ninth group contains the elements chlorine, bromine, and iodine. They all act on the vaso-motor and respiratory centers and keep up the irritability of the heart.

Hemisection of the Spinal Cord.—"The most careful experiments on the lower animals," says Ferrier ("Brain," April, 1884), "such as those of Ludwig and Woroschiloff, always leave room for doubt whether the reactions which result from the application of sensory stimuli to parts below the experimental lesion are to be regarded as signs of sensation proper, or merely of reflex action more or less general. On questions involving subjectivity, the most satisfactory evidence would be furnished by observations in man, but we rarely, if ever, meet with spinal lesions so exactly limited as to be made available for this purpose."

With the view of determining the effects of strictly unilateral division of the spinal cord in an animal as nearly human as possible, Ferrier made the following experiment on a monkey:

The animal was chloroformed, and, under stringent antiseptic surgical precautions, the cord was exposed and the left half divided midway between the seventh and eighth dorsal nerves. For eighteen days the animal remained in good health, but at the expiration of that time died suddenly. Examination revealed an extensive clot pressing on the anterior face of the pons and medulla oblongata.

The wound in the dorsal region was more or less gaping, but perfectly free from pus. The pia mater was thickened, but the cord, with the exception of the lesion described below, was entirely free from injury or inflammatory softening.

The results of the lesion were as follows:

Mobility.—On the side of the lesion (left) the leg was absolutely paralyzed as to motion, and was dragged when the animal moved about the cage with the aid of the hand and the right leg.

The temperature of the left leg was, during the first two days, much higher than that of the right. After the fourth day no difference in temperature was noticeable.

The patella-tendon reaction was at first greatly impaired or entirely abolished. Before death, however, the left patella reaction was more distinct than the right.

Sensibility.—The slightest touch or ruffling the hair of the left foot, flank, or left side of the tail, invariably attracted the animal's attention. A prick with a pin, a pinch, or a touch with a heated wire, caused it to rub the part or angrily try to seize and bite the offending cause. Hyperæsthesia of the left leg was not shown on the opposite side (right).

Mobility.—The right leg was freely moved volitionally in all directions. The animal could grip with its right foot with considerable vigor, and did so, as well as with its hands, when it wanted to free itself when held prisoner. This, however, was only true when vision was free and no impediment was offered to the intended movement of the right leg. The manifest difference between the use of the right leg, with and without vision, clearly indicated the abolition of the sense of muscular contraction, and inability to appreciate the position assumed by the leg, except with the aid of vision.

Sensibility.—In addition to the abolition of the so-called muscular sense, there was total absence of any signs of perception of contact. Pinching, pricking, or the application of heat failed to produce any sensation. There was thus total anæsthesia and analgesia of the right leg, and this extended to the right flank and right side of the tail.

The power of evacuating the contents of the bladder and rectum was not perceptibly affected.

We have thus in this case complete motor paralysis, with retention of sensibility, on the side of the lesion, and complete anæsthesia and analgesia, with retention of mobility, on the side opposite the lesion.

The Lesion.—No softening existed. The left anterior column immediately bordering the anterior fissure (the anterior median column), a small portion of the anterior root zone, and a portion of the left posterior column immediately bordering the posterior fissure, were undivided. The whole of the columns on the left side of the cord, with these exceptions, were divided.

Microscopical investigation showed ascending degeneration, characterized by atrophy of the axis cylinders without any increase in connective tissue, in the left columns of Burdach, and in the direct cerebellar tract both above and below the lesion.

Below the lesion there was disappearance of axis cylinders in the postero-lateral column of the left side corresponding to the area of the crossed pyramidal tract. No degeneration was detected in any of the other columns.

The Relation of the Nervous System to the Temperature of the

Body.—Dr. Isaac Ott ("Journal of Nervous and Mental Diseases," April, 1884) has lately made some interesting experiments in this direction. His plan was to make transverse sections of the brain from before backward. The apparatus used was d'Arsonval's calorimeter and Voit's respiration apparatus. The experiments were made on rabbits and cats. The method pursued was as follows: The animal was placed in the calorimeter and the change in the rectal thermometer noted, as well as the amount of air aspirated from the calorimeter. After an hour or two the animal was removed, etherized, and a transverse section of the brain was made. When it had recovered from the ether it was again placed in the calorimeter, and the same changes as heretofore noted. The skull was broken up by a bone forceps and the "seeker" introduced, the section being made by its blunt edge. The small seeker penetrated the cortex with but little injury to it, and, when it reached the base of the brain, was drawn transversely so as to divide the parts without injuring the cortex of either side. In the first experiment the olfactory bulbs were divided without being followed by any rise in temperature. In eight experiments in which a transverse section was made behind the corpora striata, the temperature rose in seven of them from 1° to 4⅞°, while in one the temperature fell ⅜°, probably from shock. Three experiments, in which the transverse section was made through the middle of the corpora striata, were performed. In one there was a rise of 7°, in another a rise of 1⅝°, and in the third a fall of 6⅜°. Observation made on the day following a section behind the corpora striata showed that the rise in temperature was not wholly temporary. All these experiments, Dr. Ott concludes, lead up to the belief that in the vicinity of the corpora striata there are centers which have a relation to the temperature of the body.

On Rhythmic Contractions of the Capillaries in Man.—Dr. T. Lauder Brunton ("Journal of Physiology," April, 1884) claims that, although rhythmical contraction and dilatation of the small blood-vessels, independently of the action of the heart, have been observed in the lower animals, they have not hitherto been described in man. The cases in which rhythmical pulsation, independent of the heart and of the respiratory movements, was observed were cases of marked aortic regurgitation. When the aortic valves are incompetent, the blood flows back into the heart during the diastole, leaving the pressure in the arterial system low. The heart thus receives during diastole blood from two sources—from the pulmonary veins and from the aorta—so that at the next systole a very large wave is forcibly driven into the relaxed aortic system. The alternate distension and relaxation of the small arteries render pulsation in them much more readily observed than in ordinary cases. The method of observing it is this: The finger-nail should be drawn once or twice up and down the middle of the forehead; a red streak is left, which will sometimes remain for many minutes. This streak undergoes variations of width and brightness which are very evident to the eye, and some of which coincide with the beats of the heart. In addition to this, a second rhythm of contraction and dilatation may be observed corresponding to the respiratory movements, and the rate of which is about eighteen a minute. But, in addition to these two rhythms, Dr. Brunton observed a third, which he is inclined to regard as due to independent contraction of the minute vessels. It is difficult to ascertain precisely the rate of this capillary rhythm, but, from a number of experiments, it may be said that it usually occurs approximately at the rate of one in twenty seconds. It is probable, however, that this rate is subject to numerous variations.

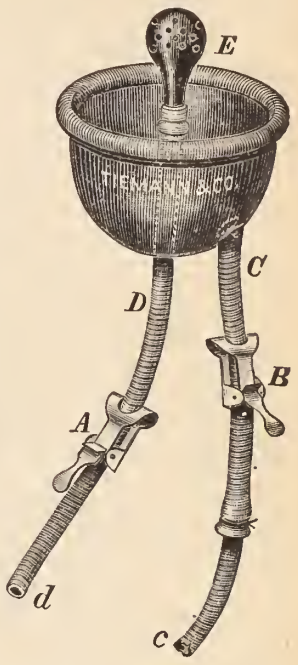
New Inventions, etc.

AN INTRA-VAGINAL CUP SYRINGE.

By E. P. Fraser, M. D.,
PROFESSOR OF GYNÆCOLOGY, MEDICAL DEPARTMENT OF THE WILLAMETTE UNIVERSITY, PORTLAND, OREGON.

The proper administration of therapeutic vaginal injections in the dorsal recumbent position, with hips elevated, is almost impossible, owing to the discomfort, annoyance, and expense attending the use of the various contrivances for receiving the injection fluid as it leaves the vagina. These are entirely overcome by the simple instrument shown in the accompanying woodcut.

The instrument consists of a cup made of soft rubber with a flexible ring around the top. Through the bottom of the cup pass the afferent tube (D), with hard rubber nozzle, and the efferent tube (C), to which is attached a waste-pipe two feet and a half long, for conveying the fluid into a receptacle under the bed or table. These tubes are supplied with patent stop-cocks (A and B). The nozzle (E) may be removed from the cup when desired. The cup is readily introduced into the vagina by compressing the flexible ring, which easily passes the sphincter muscles, and, expanding, produces sufficient pressure on the vaginal walls to prevent the escape of the fluid except through the efferent tube.



The nozzle of any style of syringe may be inserted into the afferent tube, and any quantity of water may be injected with perfect comfort to the patient. The patient lying on the back with hips slightly elevated, the fluid dilates the upper portion of the vagina and comes in contact with the entire surface, while the more sensitive portions of the vagina, vulva, and perinæum are completely protected in case very hot water is used.

In applying to the vagina or cervix glycerin, or glycerole of tannin, or any fluid application, the nozzle being removed, close the stop-cock B in the efferent tube, remove the waste-pipe, inject the application, close the stop-cock A, and leave the instrument *in situ*. Instruct the patient to allow the fluid to escape at a specified time and to remove the instrument, or allow it to remain in the vagina as a temporary support to the uterus, thus doing away with cotton and oakum tampons. Many ways will suggest themselves to the physician in which this simple instrument may be made useful. I have derived much satisfaction from its use, as with it vaginal injections and medicinal applications to the vagina and uterus may be properly administered with the greatest facility. It is gladly given to the profession, believing that it only needs to be tried to be appreciated.

These instruments are manufactured by George Tiemann & Co., New York City.

Miscellany.

The International Medical Congress.—The "Medical News," after referring to the statement made in the "Journal of the American Medical Association" in reference to the alleged resignation of Dr. John H. Packard, as Secretary-General of the Congress, says:

"We are just informed by Dr. Packard that the above statement, so far as it concerns him, is absolutely false and without foundation, and that he has written to the editor of the 'Journal of the Association' a letter for publication to that effect. While the new committee has never had any claim to public support, we yet regret that, to stimulate its waning strength, it should still further estrange public confidence by again resorting to the method of willful misrepresentation to which it owed its birth.

"Under the circumstances it is necessary for the 'Journal of the Association' to present the proof of the correctness of its statement concerning the intentions of other gentlemen before the profession can give to it unqualified belief."

The "Journal of the American Medical Association," in an editorial entitled "More Signs of Progress," says:

"In regard to the rules for regulating the conditions of membership and the working of the Congress, it is well known that all the rules relating to the latter were adopted by the new committee without change. The only change of importance proposed was in Rule 1, which related to the terms of membership. The change in this rule proposed by the committee was not satisfactory, and it is still open for further consideration and adjustment at the coming meeting of the committee on the 3d of September. In our issue of August 8th we gave two propositions that had been suggested for regulating the American Membership of the Congress, both of which were amply liberal—the one retaining the representative principle and applying it to all the national special organizations, as well as to the National Association and the State and local societies in affiliation therewith; the other opening the door of the Congress, so far as its scientific proceedings and interests are concerned, to all members of the regular profession who might choose to register and take their tickets of admission. If either of these propositions is satisfactory, let the 'News' say so. Or, if it will be more satisfactory to all parties, and will be accepted as a basis of adjustment to have the Rule 1 read simply as follows: 'The Congress shall be composed of members of the regular medical profession who shall have inscribed their names on the register, and taken out their tickets of admission,' thus making the terms of membership alike to all, American and foreign, let the 'News' and its friends indicate this, and the proposition will receive a fair consideration. They can not longer maintain their dog-in-the-manger policy on purely personal considerations without passing into history as persistent obstructionists, who place their personal prejudices above the honor and welfare of the profession to which they belong.

"The 3d of September is near at hand. If those members of the profession who so abruptly abandoned the honorable and responsible positions to which they had been assigned wish to retain those positions, and aid in maintaining the honor and interests of the profession of their country, let them move in that direction soon, or their places will be filled by others equally eminent, and the good work will move on without them. To talk of restoring the Original Committee of eight appointed by the association at Washington, and enlarged by its own action, is simply childish. It is perfectly well known that the original committee appointed at Washington is now an integral part of the present Committee of Arrangements, and has no existence in any other capacity or connection. The enlargement of the original committee by the addition of a representative from each State, and from the Medical Corps of the Army and Navy, instead of a less number selected from a few cities, neither lessens the efficiency nor detracts from the dignity of the committee, as simply a Committee of Arrangements. And such committee will proceed with its work in a true conservative liberal spirit, and will complete the preliminary organization of the Ninth International Congress on as liberal a basis and under the official leadership of as eminent and learned men as the profession in America contains."

The "Lancet" says:

"We are glad to gather from our latest information from the United States that the prospects of the International Medical Congress meeting have improved. It would be strange indeed if such a project in such a country could fail of a successful issue. The organization of the profession there may be somewhat different from what it is in older countries, and there may be ideas of professional freedom which exceed ours. There may even be questions of a personal character involved in the arrangements to be made; but that the arrangements will be great, and conceived in a magnanimous spirit, and worthy of the profession of a great country, may, we trust, be taken as already secured. One guarantee of this hopeful view being realized is to be found in the nomination of Dr. Flint as president of the Conference. Dr. Flint is so well known among us, not only by his works, but by his genial and dignified presence, that the English profession will need no other proof of the oneness of the profession in both countries, both in its spirit and its practice, than the selection by the American Medical Association of this distinguished physician for the chair of the Congress. It will be the same in other European countries. Dr. Flint has not hesitated to take long voyages in promotion of the internationa co-operation of the profession. He was as active at Copenhagen as in London, and we doubt not that the European response to the American invitation will be wide and hearty. The little differences which have arisen in America are such as the near approach of the Conference will dispel or resolve. Some of them are differences which will keep, and which can be postponed till after the Congress. The Congress itself will swallow many of them up, and give an overwhelming exhibition of the unity of the profession, such as will best at once answer and convert those who would break it up into sections and cliques, or liberate any of its members from those great traditions which have been the distinction of the profession from the time of Hippocrates downward.

"There are, indeed, powerful attractions to draw members of the profession over to Washington in 1887. The road is not an untrodden one. Many of our brethren have already crossed the water, and they bring back but one report of the greatness of the land, and the hospitality and kindness of its people, and especially of our medical brethren. Besides this, we need not remind our readers of the fact that medical art and science are in a most active state across the Atlantic. The Americans set us an excellent example year after year of disregarding the sea and its sickness in search of knowledge, and to acquire the last hints of Europe in art or science. They come so freely that we are apt to think they are only learners, and not teachers; but no mistake could be greater. They are profoundly influencing both surgery and medicine, and our own foremost leaders would be the first to admit their indebtedness to American physicians and surgeons in respect of details and of boldness in the improvement of instruments, in the great operations of surgery, in the addition of new medicines, and of enterprise in the whole field of pathology and therapeutics."

The "Medical Times and Gazette" says:

"The present medical situation in the United States has received less attention on this side the water than it deserves. But we may assure our American readers that all here who have mastered the question sympathize most deeply with them in the trouble that has befallen them. A disagreement like the present is, for many reasons, taken more to heart by our American kinsmen than it would be in England, assuming for the moment such a schism to be possible here. The American temperament differs perceptibly from ours. It is less insular and phlegmatic, more sensitive, we fancy, to the opinion of other countries, more concerned to make a good appearance before the world. Then the position of the medical profession in America is somewhat different from that which it holds in this country. Here we take a comparatively inferior place in the social hierarchy; we are overshadowed by estates and professions of higher importance and prestige in the nation's estimate. Our organization too is more oligarchical; there is more reverence among us for authority. Our leaders do lead, and if they are unanimous in any undertaking, as in the case of the London Congress, being able to count on the support of royalty, and the city, and South Kensington, and other depositories of power, they can afford to be indifferent to the support of the mere privates in their army. Even if the editor of the 'British Medical Journal' and all his council had made up their minds to control the London Congress or to wreck it, they would only have made themselves ridiculous. But in the United States the position of the profession is entirely different. There is nothing to overshadow it there. It holds a position as important and honorable in the State as that of any other calling; so that an International Medical Congress in America may be expected to enjoy a higher dignity from a national point of view than it can claim in older countries; but, at the same time, it must depend far more largely for its ceremonial success on the harmonious co-operation of the medical profession itself. Now, in the United States, the organization of the profession is purely democratic; there is no common link like that of our royal colleges, no recognized headship like that of our president of the College of Physicians, or our president of the College of Surgeons. According to the very political theory on which the State is founded, every man has as good a right to lead as any other, if he can only get that right admitted by his fellows, and for that purpose one vote is as good as another. Distinction in science and reputation abroad supply no reason to a practitioner in Texas or Colorado why he should follow a Wendell Holmes or a Weir Mitchell in preference to a Shoemaker or

a Beverley Cole. Hence a revolt of the 'rump' in the United States threatens to prove a much more disastrous affair than it would be in England, and hence we especially ask our readers' sympathy for those well and widely known American practitioners whose title to lead their profession is admitted everywhere except in the ruder and remoter States of their own country.

"We have had an opportunity of seeing several letters from distinguished American practitioners, and they all concur in expressing the most bitter grief and disappointment at the pass to which their profession has been brought. In these letters we have met with scarcely one word of anger against the dissidents who have rudely torn up the first programme of the Congress. Indeed, if we may say so without impertinence, the spirit in which the 'leaders' of the American profession, for we will still venture to call them so, have met the recent crisis is one which reflects the highest possible credit upon them. We hardly know which to praise most, their patient suspension of action until the Chicago meeting had confirmed the spirit of the proceedings of the meeting at New Orleans, or their swift and unanimous protest and withdrawal from the Congress when definite action was at length called for. The only hope for the Congress—the only possibility of maintaining the dignity of the profession—lay in such firm and united action on their part, and the effect of this action has been so favorable that there already appears to be a much more hopeful feeling in the States as to the prospects of a peace with honor. The organizers of the revolt are meanwhile making frantic efforts to prevent further resignations, and are even said to contemplate throwing over Dr. Shoemaker, on the score of his supposed unpopularity. But we may take it that no concessions on their part will be accepted short of unconditional surrender and full recognition of the authority and acts of the original committee. These are the essential preliminaries to the holding of any International Congress at all, and every day increases the prospect of their general acceptance. The sooner they are accepted the better. There will then be still two years in which to bury the hatchet, two years in which to prepare a Congress which shall 'whip creation.' We had all made up our minds for that, and shall be disappointed with anything less."

The "Pacific Medical and Surgical Journal and Western Lancet" says:

"The recent action of the American Medical Association has reduced all the arrangements for the approaching Congress to a state of chaos. In an unguarded moment it accepted the doctrine that none but members of the association, or of societies in affiliation with it, were eligible for seats in the Congress, and consequently refused to indorse the appointments made by Dr. Billings's Committee of Arrangements, who had taken the broad view that delegates should be selected from all regular practitioners. The so-called new code was made to play an important part in the discussion, and, consequently, such men as Emmett, St. John Roosa, Shrady, and Knapp were declared unqualified to become members of the Congress. In consequence of the above-quoted restrictions, the medical profession in Boston, Baltimore, and Philadelphia have refused to take any part in the proceedings, so that the American delegates will not be representative of the profession. Without doubt, the American Medical Association is the representative of the profession, and therefore the Congress convenes under its auspices; but it should be borne in mind that this latter body is an assembly of medical men, and not a convention of societies, and is not therefore bound by any code of ethics. The profession in every country has its own rules for the guidance and government of its members, and therefore the code of the American Association can not be taken as the criterion for the fitness of any man to occupy a seat in the Congress. When this question was first discussed we denied the prudence of the refusal to indorse the work of the first committee, although we admitted the power to do so; but a further consideration of the above facts, together with the recollection that the invitation was extended in the name of the PROFESSION in America, leads us to believe that every regular practitioner of medicine is eligible for a seat in the Congress. It is utterly absurd to debar men who have in former years occupied an honored place in that body, or those—such as Fordyce Barker, Emmett, Shrady, Loomis, and Jacobi—whose names are on the lips of every intelligent practitioner in Europe, merely because they hold somewhat broad views on a question of medical politics. If any one has exceeded its power, it is the American Medical Association, which was intrusted by the profession at large with the honor of making suitable arrangements, but not with the power of making laws which will exclude many of those from whom it will only be too ready to receive subscriptions.

"While the American Medical Association is thus caviling and squabbling, it seems to forget that its intended guests are being thoroughly informed of all those curtain lectures, and are not at all likely to leave their practice and cross the Atlantic for the purpose of participating in a party strife. The medical men of Europe promised to meet with those of this country for the purpose of engaging in scientific discussion, and will be amazed to learn that the noblest of America's children, who have followed in the footsteps of Æsculapius, are no longer considered members of the regular profession by their countrymen.

"Unless some satisfactory arrangement is arrived at within the next few months, the money necessary for the successful administration of the Congress will not be forthcoming, as the dissatisfaction with the action of the American Medical Association is very widely spread. We are told by the journal of the association that this is unwarrantable, for the changes made by the new committee were not of any great importance. We differ from our cotemporary in this opinion, but its truth would make the action of the association even more unpardonable, since only the most serious errors on the part of the old committee could justify the course which has been adopted.

"The proceedings of the revised committee which met at Chicago have especial interest for the profession of this State, as a serious change has been made in the *personnel* of those who were to have represented them at the International Congress.

"Dr. Levi C. Lane, whose aid in perfecting the arrangements was requested by the original committee of seven, has not only been dropped from the list of vice-presidents and from his position on the surgical section, but, as the matter now stands, is debarred from even entering the Congress as a delegate, for we learn that he was dropped on the pretext of his being a new-code man. When the New York State Medical Society adopted the new code, as it is called, and by so doing violated the tenets of the code of the American Medical Association, that association very properly denied to their delegates seats in its convention, and we at first thought that there was reason for dissatisfaction when these same men were appointed to take part in the International Congress. Further deliberation has made the difference between the two cases clear, and we believe, since the invitation was given and accepted in the name of the profession, that no regular practitioner should be excluded from a purely scientific meeting because his code differs from that of the American Medical Association.

"The committee had the power to make what appointments they chose, and in most instances closely followed their instructions, viz., to have regard for geographical representation, and not to appoint any new-code men. If, however, Dr. Lane, who had been in active correspondence with the Committee of Arrangements, and had been giving for the past year much valuable time and hard labor to the advancement of the arrangements for a successful Congress, was not reappointed because he was of the new code, a sad mistake has been made and a gross injustice has been done.

"As far as medical politics are concerned, there are no new-code men on this coast, nor in fact anywhere in the United States except New York alone.

"At the annual meeting of the California State Medical Society in 1882, the year in which Dr. Lane was elected president, resolutions were introduced to test the feeling of the members. Had these been carried, the action of the New York State Society would have been indorsed, and members have been allowed to consult with all *legally qualified practitioners of medicine*. They were, however, laid upon the table. Since that time no action has been taken, and, consequently, 'new codism' does not exist in this State. Dr. Lane is in good standing in the State Society, and the State Society with the American Medical Association, and therefore to say that he was a 'new-code' man can only have been used as an excuse to prevent his reappointment.

"A removal such as this, for such a reason, will produce an ill-feeling among the profession of California, which will only help in prevent-

ing the meeting of the Congress upon American soil being an honor to America."

Warm Baths at the White Sulphur Springs.—The managers of this popular health-resort call attention to a new method adopted by them for heating the water of the spring, which, they think, promises to be productive of the same good effects that are experienced from bathing in thermal waters. The heating is effected by steam in the vessel in which the water is to be used; consequently the heat is never so great as to cause much precipitation of the saline constituents. An additional advantage is, that more hot steam may be let in from time to time, so as to keep up the temperature of the bath.

THERAPEUTICAL NOTES.

Ergot as a Remedy for Hiccough.—Dr. E. Bonavia, of the British Indian Medical Department, in a short communication to the "Lancet," after mentioning the usefulness of ergot in various hæmorrhages, says: "Very few, however, may have heard that ergot will cure hiccough. Last autumn there was in this district an extensive epidemic of intermittent fever. The police hospital was full of fever cases. One day a policeman was admitted with an obstinate hiccough. He said he had had it for some days, and had no other ailment. I tried many remedies—sedatives, narcotics, antispasmodics, and counter-irritants. I examined his body to see whether there might not be some latent hernia in any part which might be the cause of it, but found nothing. I gave him a large antispasmodic enema, and then a strong purgative. The hiccough went on. I next tried chloroform and subcutaneous injections. As long as their effects lasted, freedom from the distressing spasm was experienced. Then it came on again with unabated force. The patient began rejecting his food and everything he took by the mouth. The case was taking a serious aspect, and I thought death would ensue. As a last resource, I ordered the liquid extract of ergot in drachm doses. I did this simply because I knew it had a decided action on muscular fiber. The first dose moderated the spasm, the second did further good, and the third or fourth stopped it altogether. The patient had some rest, but later on the hiccough returned. Three or four doses stopped it again; it never returned, and the man was well. Recently another case was admitted with a similar obstinate hiccough. My hospital assistant gave the liquid extract of ergot at once; after some doses the hiccough was stopped and did not return. I have often given this extract in drachm doses frequently repeated, and have never observed any disadvantages from it. As to the cause of this idiopathic hiccough, I think it was a chill."

The Treatment of Simple Acute Diarrhœa.—Dr. J. K. Spender, of the Mineral Water Hospital, Bath ("Brit. Med. Jour."), thinks that the management of that common malady, alvine catarrh, has never been raised to the scientific level of many diseases of rarer occurrence, so that there is always a little uncertainty in the prognosis. He refers to a formula published by Dr. David Young, of Florence, in the "Practitioner" for March, 1875; about two minims of castor-oil were combined with three or four minims of the British Pharmacopœia solution of hydrochlorate of morphine, and rubbed into an emulsion with gum arabic. To this were added spirit of chloroform and a little syrup. This dose was to be repeated every hour or every two hours, according to the urgency of the case. If the diarrhœa was chronic, the quantity of castor-oil was increased; if there was much pain, more morphine was prescribed. He has found Young's mixture extremely valuable in nearly all forms of sudden and acute diarrhœa, such as are often seen during August and September, and scarcely less useful in some chronic conditions of irritable bowel which have baffled the so-called routine remedies; but he thinks that, when the castor-oil and morphine fail, or do little good after four or five doses, it may even aggravate the malady to continue their use. Warm milk with lime-water is the best food, a mustard poultice may be put over the stomach, and there should be absolute rest in bed.

Strophanthin, a New Diuretic.—At the recent meeting of the British Medical Association, Prof. Fraser (*Ibid.*) read a paper on the apocynaceous plant *Strophanthus hispidus* (*S. kombé*, Oliver), from which an arrow-poison is prepared in many parts of Africa, called *kombè* in the Mangauga district, and *inée* in Senegambia and Guinea. The plant is a woody climber, and flowers in October and November. The follicles vary in length from ten to twelve inches, and contain from one hundred and fifty to two hundred seeds, each weighing about half a grain, and bearing a beautiful plumose tuft, placed at the extremity of a delicate stalk. They contain no alkaloid, but are rich in an active principle which the author calls strophanthin, a crystalline substance of intense activity, which seems destined to play an active part in our list of heart remedies. In physiological action it is allied to digitalin and other members of the digitalis group. It has been used, both experimentally on animals and clinically in the wards of the Infirmary at Edinburgh. The dose for hypodermic use is from one one-hundred-and-twentieth to one sixtieth of a grain.

The Treatment of Weakness of the Heart's Action.—In the course of a recent lecture on "Arterial Atheroma and Cardiac Affections," M. Lancereaux ("Union méd.") remarked that the treatment of systolic weakness should vary with the nature of the case. When it depends on dilatation of the right heart, recourse should be had especially to purgatives, for digitalis is no longer efficient, and this is readily understood at the autopsy, when the right heart is found with its walls hardened and stiffened, and remains gaping after it has been cut open. When, however, the weakness is due to atheroma of the coronary arteries, even if at the same time the heart is a little steatosed and sclerosed, digitalis acts more energetically, and it is of great service to use it in conjunction with other diuretics. The author often uses the following formula:

Scammony, Squill, Digitalis,	each	15 grains.

Divide into twenty pills, from four to six of which are to be taken daily, a milk diet being prescribed at the same time.

A Mixture for Whooping-cough.—According to a contributor to the same journal, M. H. Roger prescribes the following formula:

Tincture of belladonna		5 drachms;
Tincture of valerian, Tincture of digitalis,	each	75 grains.

For a child two years old, begin with five drops daily; increase the amount by five drops each day until it reaches thirty drops. The initial dose and the increment are ten and fifteen drops respectively for children between two and five years old and for patients who are still older. If the valerian is not well borne, tincture of musk may be used instead. Where nervous and spasmodic symptoms predominate, the author resorts to chloroform, giving to children between two and five years old from six to thirty drops daily, in two ounces of gum julep.

The Administration of Terpene.—M. Germain Sée ("Rev. méd. franç. et étrang.") gives the following formula:

Terpene	150 grains;
Alcohol, 85 per cent.	5 ounces;
Water	1½ ounce.

Two teaspoonfuls to be taken daily, in divided doses, with the meals. The author states that when the drug is administered in this way or, better still, in the form of pills, it does not produce the slightest derangement of the digestion.

Hydrochloric Acid in the Treatment of Dyspepsia.—In an article on the treatment of diseases of the stomach ("Ztschr. f. klin Med."; "Dtsch. Med.-Ztg."), Prof. Talma, of Utrecht, lays stress on fermentation of the contents of the stomach as being either the cause of dyspepsia in the great majority of instances or at least the leading factor in keeping it up. This fermentation is generally due to a deficiency of hydrochloric acid, an artificial increase of which is therefore indicated. For adults, the author recommends a mixture of fifteen grains of the acid and twenty-two ounces of water to be taken in the course of twenty-four hours. The doses had better be taken after eating, and sensitive patients may take them lukewarm. He has observed excellent results of this treatment after the failure of long-continued alkaline medication, and even in cases of ulcer or cancer of the stomach he has seen it subdue such of the symptoms as were due to abnormal fermentation.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M. D., NEW YORK.

(*Continued from page 145.*)

SPECIAL ELECTRO-THERAPEUTICS.

WE have thus far discussed the various methods of employing electricity in a general way, and there remains for us to consider how we shall proceed in employing this agent when special organs are diseased. I would preface my remarks upon this field with the statement that the curative properties of electricity must, of necessity, be modified by the pathological conditions which exist in each individual case. The prognosis is naturally more grave in some conditions than in others.

For example, a patient who has motor paralysis which is due to degenerative changes in the cells of the anterior horns of the spinal gray matter will not usually recover the power of motion completely, while he may do so if the paralysis be due to a cerebral or spinal lesion which is not accompanied by degenerative nerve-changes. Again, all forms of functional nervous derangements are more amenable to electrical treatment (if judiciously employed) than are the graver results of organic disease of the nerve-centers. A muscle which has atrophied from disuse can usually be restored, while one which has wasted from imperfect nutrition (resulting from a degenerated nerve) may withstand all efforts to improve it. The therapeutical use of electricity is subject to the same influences as that of any other remedial agent, and the prognostic conditions are not always the same even among cases of the same nature.

In previous lectures I have given you many hints relating to the differential diagnosis which you will be called upon to make in nervous diseases, and enough has been said in reference to the anatomy and physiology of the nervous system to assist you in properly interpreting abnormal nervous phenomena. I shall therefore give you, in closing, directions only as to how to employ electric currents upon different parts of the body, without entering to any extent into the causation of the symptoms which you will be called upon to treat. Remember, however, that accuracy of diagnosis is the basis of cure in a large proportion of the cases which you will meet.

ELECTRICITY IN CEREBRAL AFFECTIONS.

Experiment has shown beyond dispute that galvanic currents can be made to pass through the substance of the brain when inclosed within the skull. It is much less certain whether the same may be said of faradaic or static currents. The beneficial results which are obtained by the two latter (and possibly many of the effects of galvanism as well) upon cerebral diseases are to be attributed, in my opinion, chiefly to the alterations produced in the blood-supply of the brain. Some of the most remarkable results obtained by neurologists from the employment of electricity upon the head itself or the cervical ganglia of the sympathetic are unquestionably due to an alteration produced in the caliber of the cerebral vessels. I have never been convinced that *organic* lesions of the brain can be cured by the direct use of this agent on that organ. On the other hand, I am fully satisfied that the symptoms of cerebral hyperæmia and anæmia are directly influenced by galvanism and static electricity. I believe that any unprejudiced mind can be readily convinced of the scientific accuracy of this conclusion. I have treated many patients (who gave undisputable evidences of basilar hyperæmia by the deflections of the needle of a calorimeter), and have brought them to a state of perfect health within a space of a few weeks by galvanism of the head. The calorimeter confirmed the cure in these cases by the absence of deflection which existed before treatment was commenced. In some instances of this condition static electricity proves a very valuable adjunct to galvanism. I will give you in detail a few of the methods which, in my experience, may be employed in cerebral diseases with a prospect of great benefit to your patient.

CEREBRAL HYPERÆMIA.—First ascertain by means of a calorimeter the situation and extent of the congestion. Test all parts of the head. When necessary, do so by separating the hair and bringing the poles as closely as possible in contact with the scalp. It is not necessary, as a rule, to shave the head. In case very accurate observations are demanded, this step may have to be taken—as, for example, when a cerebral tumor is suspected to exist.

At the nape of the neck, over the mastoid processes, upon the temples, and over the forehead, no hair exists to interfere with the determination of the relative temperature of the two sides, or of different regions of the corresponding side. The calorimeter will aid you in diagnosis and treatment; if properly used, it is invaluable.

The following are the steps in treatment most generally useful:

(1) Apply the cathode to the nape of the neck, close to the skull, and the anode over the forehead. Make stabile applications for one or two minutes to each side of the forehead, the cathode remaining stabile. (2) Make labile anodal applications to the forehead transversely for one minute. (3) Move the cathode to the mastoid region of each side, place the anode centrally on the forehead, and continue each stabile application for from thirty seconds to one minute. This may make the patient dizzy. (4) Do not use a current which produces pain to the patient, but have as great intensity as he can comfortably bear. (5) Never reverse the current when the poles are on the head.

These applications may daily be alternated with "*insulation*" and the "*electric head bath*," if you possess a static machine. The sittings should occur daily until the symptoms are cured, and the calorimeter ceases to show its previous deflection.

It is sometimes well to *stimulate the superior cervical ganglion* by placing a small anode in the fossa behind the

angle of the jaw, and the cathode on the seventh cervical spine, and to slowly interrupt the current. Caution must be exercised against employing too strong currents.

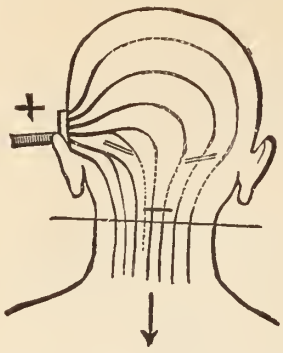


Fig. 40.—A Schematic Representation of the Distribution of an Electric Current applied unilaterally through the Head (after Erb). The anode (+) rests above the ear of the left side. The cathode (—) is supposed to be at the nape of the neck, and to exert its influence as far as the line drawn horizontally across the neck.

Finally, active *faradization of the limbs* is sometimes necessary, in order to draw the blood to the limbs. It is not well to employ this step if it causes an elevation of temperature.

The effects of this treatment should be to relieve the pain or sense of fullness in the head, the vertigo on rising, the mental confusion or distress, the insomnia, and the many other symptoms peculiar to this condition; and to steadily reduce the calorimeter deflections when the poles are in contact with homologous parts.

Cerebral Anæmia.—I should advise you to begin the use of very weak galvanic currents after an attack of embolism. I believe that currents of this kind sent transversely through the head from the temples, and occasionally in the antero-median plane, assist in absorbing the collateral œdema and cause a diminution of the collateral hyperæmia. I prefer to use the cathode on the side of the embolic obstruction when transverse currents are employed. In my opinion, it tends to promote absorption and to contract the vessels far more than the anode. The paralyzed muscles should be treated separately, by methods given in detail later.

Some four years ago Löwenfeld published some deductions relative to the action of galvanic currents upon the brain, based upon experimental researches. Although their accuracy has been justly called in question by authors of note, my own experience leads me to confirm them in part and to attach some importance to them. These conclusions were as follows: (1) Anode at forehead and cathode at neck causes contractions of the vessels of the pia; (2) anode at neck and cathode at forehead causes dilatation of the vessels of the pia; (3) when transverse currents are employed, the cathode causes contraction of adjacent vessels, and the anode dilatation.

When cerebral anæmia of a *general character* exists (as a manifestation of poverty of the blood, defective heart-power, etc.), general faradization, central galvanization, and static electricity by insulation are often of material benefit. The removal of the cause by judicious medication, etc., is, of course, vital to successful electrical treatment.

Hemiplegia of Cerebral Origin.—A very large proportion of patients with hemiplegia from cerebral causes owe the paralysis of their limbs to hæmorrhage, softening, or

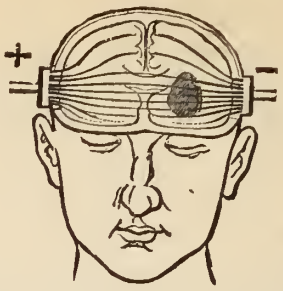

Fig. 41.—A Schematic Representation of the Course of Electric Currents sent Transversely through the Head (after Erb). The cathode (—) is represented as placed on the side of the lesion.

embolism. The electrical treatment should be directed to both the brain and the muscles. It should not be commenced (save in the case of embolism) until a month has elapsed since the attack. Each patient's susceptibility to the agent should be carefully studied; and the strength of current employed should be modified accordingly. The muscles may be treated by faradization or galvanization, or by the static current (indirect sparks being drawn from the paralyzed limbs). The brain should be subjected to galvanization only, or to static insulation.

If the patient fails to show improvement within a month after the treatment has been daily applied, or if the improvement of the first few days is rapidly lost in spite of continued treatment, the prognosis, as regards marked amelioration of the paralysis by electrical applications, is grave.

Hemianæsthesia is best treated by the wire-brush upon the dry skin in connection with the secondary faradaic current. I have also obtained some remarkable effects with the combined current (as before stated), and also with the static current, in cases where the faradaic current was ineffective.

Post-paralytic rigidity (occurring late) is the result, in most cases, of secondary changes within the spinal cord. The supervention also of pigmentation of the nails, œdema, a shiny skin, disease of the joints, and other evidences of trophic alterations, points to a serious and often permanent destruction of the nerve-centers.

Hints which have been given under the head of general electro-therapeutics will guide you in modifying the treatment according to the exigencies of each individual case. The remarkable improvement which some hemiplegics obtain through the instrumentality of electrical treatment should impress you with the necessity of employing it long enough to ascertain whether its continued use is indicated.

Monoplegia or Monospasm.—These conditions are particularly indicative of cortical disease. The muscles affected are a guide to the convolution attacked. I have covered this field in previous lectures.* The indication in such a case is to improve, if possible, the nutrition of the diseased part directly by galvanism, and also to stimulate the muscles functionally associated with it. I employ for this purpose a "medium" electrode over the diseased con-

* See "Med. Record," May and June, 1884.

volution, the indifferent electrode being placed over the center of the sternum. It is my custom to employ both poles to the head for an interval of two minutes each at a sitting. The monoplegic limb may be treated by labile galvanic applications, the wire-brush and faradization, or the indirect spark by means of a static machine.

Duchenne's Disease.—The morbid changes in the nuclei of the medulla which accompany bulbar paralysis may, in some cases, be held in check for a while and the symptoms markedly improved by placing the positive electrode (of large size) at the nape of the neck and as close as possible to the foramen magnum, and applying the negative electrode (covered with absorbent cotton and attached to a long handle) successively to the pharynx, fauces, tongue, cheeks, and lips. As strong a current as the patient can easily endure should be used. The duration of the sitting should not exceed five minutes. It is well to complete the sitting by passing transverse currents through the neck, so as to excite the muscles concerned in deglutition. Some authors recommend the employment of currents through the head, both longitudinally and transversely.

ELECTRICITY IN SPINAL AFFECTIONS.

There are various ways of bringing the spinal cord under the influence of electrical currents. The method of application selected in any individual case will depend somewhat upon the symptoms which the patient presents, and also upon the character and seat of the lesion. The diagrammatic cuts of Erb, which illustrate the diffusion of electrical currents, show in a graphic way the effects of close approximation and wide separation of the poles. We may also modify some of the morbid conditions of the spinal cord by electrization of the extremities when the indifferent pole is placed over the spinous processes. It is well to increase the size of the electrodes proportionately to the strength of the current employed.

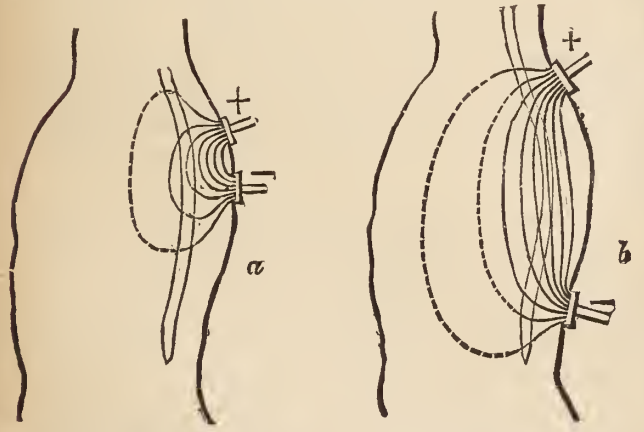

Fig. 42.—A Schematic Representation of the Distribution and Density of the Threads of Current with regard to their entrance into the Spinal Cord (after Erb). In *a* the poles are placed near each other. In *b* the poles are more widely separated. The size of the electrodes shown in the cut is the same for both the anode and cathode.

Fig. 42 illustrates the effect of separation of the poles when applications of electricity are made to the spinal column. Some of the threads of current depicted are rendered ineffective on account of their diffusion. This is made more apparent in Fig. 43.

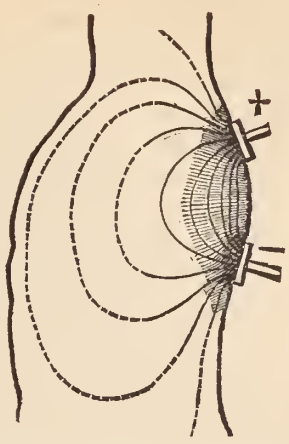

Fig. 43.—A Schematic Representation of the Density of the Current upon application of the Electrodes to the Same Surface and in Close Relation to Each Other (after Erb). The dotted lines indicate the ineffective threads of current. The shaded portion represents the zone of greatest intensity.

ELECTRIZATION OF THE SPINAL CORD.

To treat properly of the various methods which may be used when the application of electrical currents as a therapeutical measure for the relief of spinal diseases seems indicated, it would be necessary for me to enter into greater detail regarding spinal diseases than the time allotted to these lectures will permit of. I am reluctantly forced, therefore, to summarize somewhat hastily the main points which my experience with this agent leads me to indorse. Most of you are probably already familiar with the pathological changes which exist in connection with the more common diseases of the cord; but, if any of you are not so, they should first be studied and thoroughly mastered before you can hope to successfully combat them.

Galvanic currents are of greater service in the treatment of spinal diseases than faradaic or static—chiefly on account of the depth of the tissues affected and the chemical and molecular changes which galvanic currents tend to induce.

Spinal electrodes should be of large size.

The applications may be either stabile or labile, the former being of the greatest benefit when the spinal lesion is circumscribed in extent, and the latter when a larger part of the spinal cord is affected. If labile applications are indicated, the movements of the electrodes should be made somewhat slowly.

In directing galvanic currents to the *cervical* and *upper dorsal segments* of the cord, it is well to place one electrode of medium size behind and below the ear alternately on the two sides of the neck, while the other is applied to the spine.

Points of tenderness to pressure along the spine should be subjected to stabile applications of the anode. They should be sought for in each individual case with care and separately galvanized.

The *strength* of the currents employed should be modified in individuals by the condition which is presented for treatment. Weak currents of from two to five milliampères

act best, as a rule, when excessive irritability of the organ exists; chronic pathological conditions respond better to currents of greater intensity. I often use eight to twelve milliampères of current in chronic cases.

It is advantageous, in some subjects, to make *electrical applications to the limbs* when the cord is affected. Stimulation of the peripheral nerves and the muscles connected with the segments of the cord involved should be particularly aimed at, although the electrization of the skeletal muscles and the skin should not be exclusively confined to the limits thus indicated. It is my custom to employ the "*combined current*" (previously described) when applications to the limbs are thus made. This form of current is particularly indicated when the muscles exhibit a tendency toward atrophy. The electrode which rests upon cervical or lumbar enlargements of the spine should be of large size, while that used upon the limbs should be of medium size, so as to direct the combined currents to the nerves or muscles affected.

If *galvanism alone is used upon the limbs* in spinal disease, it is often beneficial to the patient to break the current by an interrupting electrode, or to reverse its direction by means of the commutator.

Some authorities advocate *faradization of the vertebral region and of the limbs* in conjunction with galvanic applications. I have seen in a few instances some remarkable effects follow the employment of the wire-brush alone in polio-myelitis of children, and I can see no reason to doubt its occasional efficacy in other forms of spinal disease.

In some unexplained way the excitation of muscular action and stimulation of the cutaneous nerves exert in many instances a remedial effect upon lesions of the spinal cord.

It is not always possible (as, for example, in polio-myelitis) to excite muscular action by faradism alone. In these cases interrupted galvanic currents, or the "combined current" (galvano-faradaic), will accomplish the desired end. I have repeatedly observed beneficial effects of this treatment in locomotor ataxia, and Rumpf has published some cases which sustain this view in which the wire-brush was used upon the arms and legs daily for about five minutes.

In all acute *inflammatory disorders of the cord* I deprecate the use of electrical applications. When the acute stage has passed, or when the disease has assumed a chronic type, many of the effects of the disease (as, for example, muscular paralysis, rectal or vesical complications, incipient caries, anæsthesia, etc.) may often be greatly relieved by its judicious use. The current-strength employed in such cases usually varies from five to eight milliampères. The applications should be made daily. When possible, it is important that you localize early the seat of the structural lesion and concentrate the treatment, for a while at least, upon the segments of the cord involved. The muscles, skin, bladder, rectum, etc., should be separately subjected to the influence of electricity in case they exhibit a loss of function.

ELECTRICITY IN PARALYSIS OR PARESIS.

Hypokinesis may be due to many different conditions, hence its electrical treatment and prognosis must vary in accordance with the cause which excites it. You should remember that paralysis of a muscle is only symptomatic of other conditions, such as lead-poisoning, diphtheria, hysteria, mechanical pressure upon a motor nerve, severance of a motor nerve, destructive processes or inflammation within the motor cells of the brain or spinal cord, and changes in the vessels. All of these tend to impair either the generating power of a motor center, or the conducting power of a motor fiber.

Respecting the application of electricity to the seat of central lesions (*i. e.*, lesions of the brain or spinal cord) in cases of motor paralysis, De Watteville pertinently remarks as follows:

"It is true that we have too often but a very imperfect idea of those processes in the nerve-centers upon which the symptom depends, and that we have no right to assume that the current has any specific curative influence upon any one of them; still, as a justification for central treatment in such cases, we may plead our very ignorance, we may urge the poverty of our therapeutical arsenal in arms wherewith to combat our enemy, and may also invoke the possibility of at least staying its progress by promoting nutrition of the surrounding portions of the nervous structures threatened by its invasion."

When the lesion directly affects the conductivity of a nerve, we have reason to believe that the direct influence of electrical currents upon the lesion tends to overcome the resistance offered to conduction by the disease-process, and facilitates the subsequent transmission of voluntary stimuli.

There are certain general rules that are applicable to the electrical treatment of paralysis of motility. These may be stated as follows:

1. The treatment should not be alone confined to the region of the paralyzed muscles.

2. The seat of the exciting lesion should be ascertained early, if possible, and subjected to the influence of this therapeutical agent in an intelligent way.

3. If the motor paralysis is accompanied by anæsthesia, hyperæsthesia, or other sensory disturbances, or if the vaso-motor system of nerves be apparently implicated, the wire-brush may often be used with advantage upon the skin in the vicinity of the lesion, and also over the muscles paralyzed.

4. Faradaic currents (provided they excite muscular action), or the cathode-pole of a galvanic battery (with interruptions of the current), are of use in exciting the conductivity of the nerve-tracts affected. Static electricity is also of great utility in inducing muscular contractions, and is less painful than faradism or galvanism.

5. The "combined current" (galvano-faradaic) is chiefly of service in overcoming trophic disturbances, which often manifest themselves in connection with motor paralysis.

6. I prefer labile applications to stabile in applying either faradism or galvanism to the muscles. Stabile applications are preferable to labile when the brain, spinal cord, or peripheral nerve-trunks are to be influenced.

7. Never begin the use of electricity immediately after the onset of paralysis (when due to a central lesion). It

is always best to wait until all danger of exciting a recurrence of the attack by stimulation of the nerve-centers has passed.

(*To be continued.*)

Original Communications.

PYROGALLIC ACID AND COLLODION: A TREATMENT FOR PSORIASIS.

By GEORGE T. ELLIOT, M. D.,

ASSISTANT VISITING PHYSICIAN, NEW YORK SKIN AND CANCER HOSPITAL; ATTENDING PHYSICIAN, DEMILT DISPENSARY, ETC.

For many years innumerable attempts have been made by dermatologists to obtain some form of application for the treatment of diseases of the skin which would be an advance on, and which could also supersede, the usual time-honored methods, such as ointments, etc., accompanied as they are by certain objectionable features which cause their use to be, as a rule, a source of considerable annoyance. The soiling of the linen, the discoloration of the skin, etc., attending the application of some of the most useful medicaments, have always been serious evils. To remedy these, or at least as much as possible to remove them, we have had in the past few years many preparations brought forward in which the drug to be used has been incorporated in gelatin, traumaticin, etc., or has taken the form of plasters, as recommended by Unna, and known as "Unna's Pflastermull." Each of these has had its supporters, and has enjoyed reputation and extensive use for a longer or shorter period of time, finally to be relegated to a greater or lesser disuse, leaving dermatologists still seeking for that application which would be generally acceptable as regards cleanliness, and in which the proper action of the drug used would not be interfered with or diminished. Many skin diseases, owing to their chronicity and the length of time necessary to cure them, especially call for some such application, for the continued use of a treatment offensive alike to the sight and smell can only disgust the patient, until he finally prefers his disease to the remedies used therefor. Among these diseases, psoriasis is prominent. For its cure a little of everything, both externally and internally, has been recommended, from the old-time tar—which, however, always gave most satisfactory results—to the more recent chrysarobin and pyrogallic acid.

It was in regard to the treatment of this disease that, dissatisfied with the methods in practice—objectionable features being to a certain extent present in all of them—I sought to remedy them, not by any new medicament, but by a new combination of remedies already in use. Though speaking of the treatment of psoriasis, I do not, however, intend to review the many methods which have been recommended, these being dealt with *in extenso* in works on general dermatology, and I desire to limit myself only to the method which I have been using entirely for now nearly a year, being one which has given me most satisfactory results. Still, I would briefly mention one method, since the formula which I use differs from it only in regard to its principal and active ingredients.

A solution of chrysarobin in collodion was first used and recommended in Europe by Sesemann, and here by G. H. Fox, who improved its action by the addition of salicylic acid. It has enjoyed, since first brought out, deservedly great repute, has been extensively used, and is a valuable addition to our list of remedies. Unfortunately, however, the chrysarobin now obtainable in the market is so unreliable and impure that the service which it formerly rendered has become very uncertain and much diminished, so that the results, even from strong solutions, are far from satisfactory. I have found another objection to chrysarobin, and that is, that only a portion of it is soluble in the collodion, and, when used in a ten-per-cent. or twenty-per-cent. solution, there is always a considerable sediment, which causes it, when shaken up, to be of a more or less gruelly consistence. This, naturally, is an objectionable feature, depriving the application, to a certain extent, of cleanliness in its appearance, and giving the skin painted with it an unsightly look.

These objections I sought to remedy, and, having always had a predilection for pyrogallic acid, I determined to substitute it for the chrysarobin. This acid was first introduced into dermatology by Jarisch, and was recommended by him for the treatment of psoriasis, but it has since then been used in many other diseases of the skin. It was received with great favor at first, and the benefits derived from it were extolled, until a few unfortunate deaths occurring from its application, as reported by Neisser, Besnier, and others, caused dermatologists to become chary in its use and to prefer the safer chrysarobin. If used properly, however, there is no more danger from the one than there is from the other. The deaths reported were indubitably due to the careless manner in which the acid was employed, a ten-per-cent. ointment having been rubbed in over the entire body every day, a procedure which might in all probability give some unfavorable results, even if some less absorbable or more innocuous drug had been used. In Jarisch's hands, and in the practice of Kaposi and others, I have always seen it give the greatest satisfaction, and I have not as yet seen any untoward result occur. On the contrary, in the cases which I saw treated by them, and in my own cases, I have only been able to observe a quicker and more complete disappearance of the eruption when pyrogallic acid was used.

So far as I have been able to ascertain, it was received with little favor in America as a remedy for psoriasis, possibly owing to the already mentioned deaths occurring from its use, and also to its always having been made up as an ointment, a method of application which, to say the least, is very disagreeable on account of the black color which it acquires after exposure to the light, and the destruction of the patient's linen. The dark pigmentation remaining after its use and the ease with which a dermatitis arose were also potent objections to it.

In order to avoid and remedy, if possible, these objections, I determined to try an application of pyrogallic acid dissolved in collodion, substituting it for chrysarobin. The

immediate and patent advantages shown have caused me to use this solution in all cases of psoriasis to the exclusion of every other method of treatment. The strength of the solution has varied from 10 to 15 per cent., and I have not yet found it necessary to increase this strength. The formula reads as follows:

℞ Acidi pyrogallici..... 3 jss.–3 ij;
Acidi salicylici..... 3 ss.;
Collodii flex..... ℥ ij.
M. et ft. sol.

The first advantage which I noticed was the complete solubility of the pyrogallic acid, the solution being perfectly clear and without any sediment whatever. It was at first limpid and clear, but, after exposure to the light, it gradually became brown in color, and I found it was better to keep it in a dark-colored bottle. After applying it to the skin it becomes darker, and may even appear black.

The salicylic acid, which had been added to the chrysarobin collodion by Dr. G. H. Fox, I retained in the pyrogallic collodion, owing to the peculiar action which it exerts on the horny epidermis, though it has itself no direct curative effect over the disease. Unna, of Hamburg, drew attention in 1883 to the fact that certain of the medicaments called antiseptics, when used in the strength necessary for antisepsis, had a peculiar effect upon cornification, preventing keratoplasia through their possessing a keratolytic power. Whether this power acts by dissolving out the keratohyalin necessary for cornification, or whether it prevents its formation, is still *sub judice*. However, when my attention was directed to the fact by his article on "Dermatoplasie und Keratoplasie" ("Berlin. klin. Wchschr.," No. 35, 1883), it offered me an explanation of a condition which I had often observed when using salicylic acid in the treatment of various forms of skin diseases. A surface to which it was applied could be brought to a certain point in healing, and then a retardation in cornification would ensue. Epidermis would form, but it remained soft and easily removable, and this condition would persist as long as the salicylic acid was used. If it was laid aside, and some bland application was made, however, keratoplasia would rapidly follow. This action led me to retain it in the pyrogallic collodion, as it occurred to me that its presence might have the effect of diminishing, or perhaps preventing, the formation of epidermic scales on the psoriatic plaques or lesions, thus allowing the pyrogallic acid to act more directly upon the affected cutis.

In using the pyrogallic collodion, the patient should be directed to first remove all the scales by taking a warm bath. After drying the body carefully, the solution should be freely applied to the lesions, the application extending one fourth or one half an inch beyond the edges of the psoriatic spots. This can be done by using a moderately stiff, bushy brush. Care should be taken that the lesions are completely covered with the solution, and the parts which have been painted should remain exposed until they are perfectly dry. A renewal of the application may be made every day if desired, but I have found it quite sufficient to repeat it every second or third day. Removal of the collodion still adhering to the skin is of course necessary previous to each fresh painting, since it is advisable to treat the psoriatic lesions, and not the old coats of collodion covering them.

In all the cases of psoriasis in which the pyrogallic collodion has been used there has been no soiling of the patient's linen. After the application has dried, if it were not for the color, which gradually darkens, its presence would not be noticed. I have not seen any dermatitis follow its proper use in any case. One patient, however, for whom the solution was prescribed as an application for a spot of herpes tonsurans, applied it industriously three times daily, though otherwise instructed, and, as might have been expected, caused a dermatitis to light up around the lesion. In no case have I seen any pigmentation remain after the cure of the psoriatic lesions; the surface to which the pyrogallic collodion had been applied differed in no way in appearance from the surrounding skin. If the solution is improperly used, however, and dermatitis lighted up, pigmentation may easily occur; consequently it is necessary to be careful not to apply it so often that undesired results may ensue.

The results obtained in treating psoriasis with the pyrogallic collodion have been in every way satisfactory. A great change could be seen in the lesions after a few applications. There was an absence of scales and a diminution in the hyperæmia, and the plaques and spots appeared less elevated. The time which was required in curing the psoriasis by means of this solution has naturally varied according to the extent of the disease and the length of time which it had existed. Any rule in regard to it could scarcely be made. The quickest results which I have obtained were in psoriasis guttata, and the slowest in a case of psoriasis nummularis of long standing. In cases where the eruption is universal, or nearly so, it is of course advisable to treat the various portions affected *seriatim*. The results will be just as satisfactory, only the time required will be longer.

In one other form of skin disease, herpes tonsurans, I have used this solution of pyrogallic acid, and with most gratifying success. Its effect upon the lesions has been surprising, two applications having been sufficient in the majority of cases to effect complete cure.

In addition, I can only say that I trust this combination of pyrogallic acid and collodion will obtain a greater recognition for the acid than it has heretofore enjoyed with us, and I hope it will prove as satisfactory to the members of the profession as it has to me in both hospital and private practice.

SOME OBSERVATIONS WITH REFERENCE TO CHOLEROID ALVINE DISCHARGES.

By FRANK S. BILLINGS,
PATHOLOGIST TO THE NEW YORK POLYCLINIC.

On the 22d of June, Dr. J. H. French, of the Fourth Medical Division, Bellevue Hospital, sent some material for examination to the Patho-biological Laboratory of the New York Polyclinic.

The following remarks accompanied the material:

"The specimen is from a patient admitted last night

suffering from acute gastro-intestinal catarrh; discharges very frequent, accompanied with emesis; great thirst."

Examination of material:

It had the usual appearance of rice-water stools, almost inodorous, and was full of yellowish-white flocculi.

Reaction: *Strongly acid.*

Microscopical examination of the flocculi revealed the presence of various forms of cocci, diplo- and strepto-cocci, and bacilli, *but absolutely nothing that could be called a comma.*

As it was late in the evening, the material was at once corked and placed in an ice-chest, very near the ice. It was our intention to filter it very carefully in the morning and then sterilize, and to use this material in its natural acid and a reduced alkaline condition as a cultivating medium for the Koch and Finkler commata.

In this regard I made an unexpected and perhaps excusable error, which is, however, *practically*, quite suggestive.

The reaction of the material should have been taken the next morning, and it should have been filtered before a microscopic examination was made. On the contrary, we at once filtered it, and threw the residue away.

We next tested the reaction. It had become *alkaline* of itself.

The questions now arise:

1. What caused this change in reaction?

2. Would it have occurred *intra vitam* in the same patient had he not improved and recovered?

3. Would comma bacteria have then appeared? (The Finkler comma has not yet been proved to have universal *diagnostic* value even for cholera nostras, as can be accepted for that of Koch with regard to cholera asiatica.)

4. Were the germs of any form of comma bacteria present, and would they have developed in the mass had it been allowed to stand in an ordinary temperature after it had become alkaline; or, in other words, *were there comma germs in it, intra vitam, needing only an alkaline condition of the intestinal contents for their development?*

5. Aside from all known connections with comma bacteria in the alvine discharges of acute catarrhal diseases, these experiments indicate still another question which may have important clinical bearings, viz.: *If in such cases the discharges suddenly become alkaline instead of acid in their reaction, is it not an indication of a fatal termination, or, at least, of a most questionable prognosis? If, on the other hand, the discharges become acid after having had an alkaline reaction, may it not indicate a favorable change in the disease?*

Both of the comma bacteria develop spores at certain periods of their existence.

To prove that the filtered material, which contained all its original elements in solution, and had acquired an alkaline reaction, was a suitable medium for the development of these commata, it was boiled several times in appropriately closed test-tubes, then allowed to stand for forty-eight hours in the ordinary—extraordinary—heat of the laboratory. It remained absolutely clear and amber-colored.

1. The tubes were then carefully inoculated with purely cultivated Koch and Finkler commata.

2. In twenty-four and forty-eight hours there were indications of their development in the opalescence of the media.

3. Gelatin tubes were again inoculated from these and both commas developed in the recognized manner.

These very few experiments, but still sufficient in number, prove the conclusions so well known of Koch and others with regard to the biological necessities of the two commas.

They also show that the discharges from ordinary choleroid cases have, in their serum or fluid, every requisite for the development of these bacteria as soon as the intestinal contents assume an alkaline character, or it is artificially produced, as has been also shown by animal experiments. The attention of clinicians is called to these points.

It certainly is not out of place for me to say that we are prepared to supply boards of health, hospitals, or physicians with any of the forms of gelatin or blood-serum desired for experiments, or to conduct any examinations that may be desired. We are especially desirous of obtaining material for study as above described.

CATARRHAL AFFECTIONS OF THE NASAL PASSAGES

AS A CAUSE OF

PULMONARY PHTHISIS,

WITH SPECIAL REFERENCE TO THE QUESTION OF HEREDITY.*

By WILLIAM CHAPMAN JARVIS, M. D.

The ætiology of pulmonary tuberculosis, a subject always replete with interest to the clinical investigator, has naturally received a deeper significance since the discovery of the *Bacillus tuberculosis.* Despite, however, the positive character of Koch's results, there remains, according to his own admission, much yet to be learned concerning the prætubercular conditions which determine the development of the tubercle bacillus.† These conditions, variously and oft-times vaguely referred to by such terms as tubercular disposition, predisposition, heredity, environment, etc., it would appear, are the principal avenues through which this momentous question, affecting the lives of so many thousands in our crowded city and elsewhere, is to be approached.

Several years ago, while studying the cause and complications of nasal diseases, my attention was attracted to the co-existence of bronchial with nasal catarrh, and somewhat later to the association of nasal disease with pulmonary phthisis.

These earlier impressions did not assume the shape of convictions until the reliable evidence I am about to present for your serious consideration was forthcoming.

In view of the light already thrown upon the question of the ætiology of tuberculosis through Koch's bacillary investigations, I have deemed it profitable to review some of the evidence he has offered us concerning the disposition and predisposition to phthisis.

As regards the question of the physical conditions fa-

* Read before the American Climatological Association, May 27, 1885.

† "Mitthcilungen aus dem kaiserlichen Gesundheitsamte."

vorable for the development of bacilli, we are informed by Koch that pent-up secretions, removal of the protective epithelia of the bronchi, abrasions, etc., are to be considered the proper soil—the "*geeignete Boden*"—for the lodgment and growth of the deadly tubercular plant. Now, these conditions will be recognized as the common results of catarrhal inflammation of the upper and lower air-passages. One or more of them are frequently observed in nasal catarrh, and may be also associated with catarrhal phthisis when taken in the popular sense of the term as taught to us by Dr. Alfred L. Loomis.

In certain cases we find pulmonary tuberculosis rapidly following in the train of a catarrhal bronchitis, while others will, apparently, resist the inroads of the bacillus for many years.

In treating my subject I shall begin with the nares and endeavor to distinctly trace the effects of nasal catarrh upon the larynx, and then in turn explain the relation of the resultant laryngeal disease to bronchial catarrh, catarrhal phthisis, and, finally, pulmonary tuberculosis.

The relations of the nostrils to the lungs is so intimate that we are not surprised to find Koch involuntarily addressing his attention to the nose for a partial solution at least of the question of the ætiological relations of the bacillus to pulmonary tuberculosis, with the remark, "Air inhaled through the nose is deprived of disease-germs, and nasal respiration, therefore, constitutes a positive protection against infection by reason of the retention of the infectious material by the nasal mucous membrane." Conspicuous among the complications traceable to nasal catarrh, and bearing upon the question of the causation of pulmonary phthisis, is *chronic irritative hyperæmia of the larynx.* I can not at present enter into a description of this affection, or fully explain how it is brought about by the entrance of nasal mucus into the larynx. I called especial attention to this condition in a paper read before the American Laryngological Association, session of 1881, to which I must refer you.*

This affection is usually observed as a peculiar red discoloration of the normally pearly white vocal cords, and, when found, constitutes an excellent guide for the determination of the amount of congestion of the general laryngeal mucous membrane. Chronic hyperæmia of the larynx frequently develops attacks of acute catarrhal laryngitis, and this affection in turn often involves the tracheal and bronchial mucous membrane by inflammatory extension. In other words, recognizing the larynx, with certain modifications, as the upper portion of the lungs, catarrhal inflammation of this organ clearly constitutes a menace to the integrity of the entire pulmonary tract. The laryngoscopic study of the pathological processes concerned in the production of laryngeal hyperæmia and its common sequela—laryngitis—is, therefore, required to throw light upon the pulmonary diseases following in its wake.

Nasal stenosis and defective nasal drainage are the two most important indirect agents concerned in the production of this affection. The manner in which these intra-nasal disturbances lead to laryngeal and lung complications is principally by habitual mouth-breathing, the irritating action of nasal mucus in the larynx, and inflammatory extension from the posterior nares.

The part played by nasal mucus as an ætiological factor in the production of laryngeal and pulmonary disease is well pronounced and very important. The constancy with which chronic irritative hyperæmia of the larynx occurs as a result of chronic nasal catarrh encouraged me to make the statement that the simple discovery of this peculiar congestion was, as a rule, sufficient evidence of the existence of a chronic nasal catarrh.

The manner in which chronic hyperæmia of the larynx is induced through defective nasal drainage is exceedingly simple, and is best understood by carefully studying the direction of the several anatomical planes of the upper air-passages. I will refer you to a paper read by me before the New York Academy of Medicine, in which is given a detailed description of this system of drainage.*

I may simply state in passing that the disturbances to nasal drainage originating from a nasal catarrh prevent the natural disposition of nasal mucus, and, consequently, permit it to enter the larynx. Now, nasal mucus in the larynx is a foreign body, and as such invariably gives rise, by prolonged irritation, to a familiar train of signs and symptoms. Foremost among the signs stands, as I have already pointed out, chronic irritative hyperæmia of the larynx. The larynx naturally resents the invasion of its territory by irritating nasal discharges, and we have, as one of a number of *well-marked symptoms*, a constant inclination to "clear the throat." This act in itself may constitute an additional irritant by the rasping effect of the effort upon the vocal cords. The part played by habitual mouth-breathing as an excitant of laryngeal disease is simply that resulting from the absence of those conditions so essential for the purification and preparation of the respired air, and attributable to prolonged nasal stenosis.

Having briefly presented the most conspicuous causes which serve to account for catarrhal disease in the larynx, the next step would naturally be to study the nasal complications responsible for the existence of the laryngeal affection.

Among these may be mentioned deviation of the nasal septum, turbinated hypertrophies, polypi, adenomata of the vault of the pharynx, etc. The proper consideration of either one of these conditions, taken alone, would cover many pages. I shall, therefore, be compelled to entirely omit the consideration of some, and only briefly accentuate those most commonly concerned in the production of laryngeal and pulmonary disease.

Hypertrophy of the turbinated tissues is an almost invariable concomitant of the moist forms of nasal catarrh. It may stand either alone or, as is commonly the case, exist as the result of a deviated septum. The co-existing mouth-breathing, hypersecretion, and disturbed nasal drainage will, of course, be governed by the location and amount of the turbinated hypertrophy. Passing promptly to the consider-

* "Archives of Laryngology," vol. iii, p. 148.

* "Medical Record," March 14, 1885.

ation of the second condition, the deviated septum, we are at once confronted by the most active and common agent concerned in the production of pulmonary and laryngeal disease. This condition differs from turbinated hypertrophy in being both a cause and result of catarrhal inflammation. Its existence, furthermore, implies the co-existence of a turbinated hypertrophy, barring, of course, recent traumatic deviations and extra-nasal distortions of the septum.* I have already had occasion to explain how a deviated septum, through *pressure irritation*, excites catarrhal inflammation.† Its action may be, to employ a homely example, compared to that of a shoe-button impacted in the nostril. The deviated cartilaginous spur, like this familiar foreign body, presses against the exceedingly sensitive surfaces of the turbinated tissues, invariably exciting and keeping up a certain amount of inflammatory action.

Thus we have a system of reciprocal irritation provoking and prolonging a nasal catarrh. For want of a better expression, I have called this *pressure irritation*, and I trust the term may recall to your mind the pathological process it indicates when employed in this paper.

The rôle played by the turbinated tissues and septum in the production of rhinitis hypertrophica was noted by me in a paper read before the American Laryngological Association, session of 1880; and the ætiological relation of the nasal septum to diseased turbinated bodies was also satisfactorily demonstrated by Dr. Harrison Allen, though in a way differing from my own, in the same year.

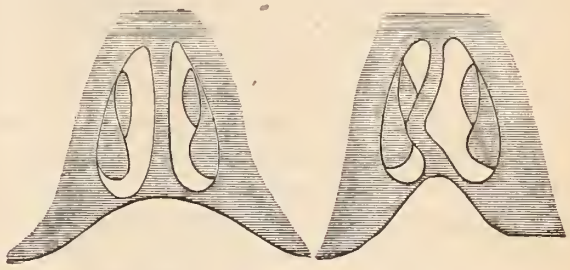
Having determined the ætiological significance of the deviated septum in nasal catarrh, for a more detailed description of which I must refer you to my earlier papers on this subject, add another factor which serves in turn to account for the deviated septum, and requires a brief consideration—namely, heredity.

The term heredity, usually furnishing much material for uncertain speculation and little opportunity for satisfactory demonstration, has, in this connection, assumed a more definite meaning by reason of much corroborative testimony always at hand.

This evidence has convinced me that the deviated septum is frequently transmitted from parent to child.

In 1882, while engaged relieving the sufferings of a young woman, brought on by a congenital occlusion of the nares, my attention was attracted to an abnormal contraction of the superior maxillæ. In reporting the case I laid great stress upon the possibility of the chronic coryza and turbinated hypertrophies being associated with this condition as cause and effect.‡ Since that time, by careful investigation and comparison, I have been enabled to supply the necessary links in a chain of evidence which has demonstrated that one of the most common causes of catarrh is discoverable in the conformation of the hard palate. This peculiar malformation I find to be transmitted from parent to child with remarkable regularity, and its intelligent recognition and proper appreciation enables one to most satisfactorily account for a large number of catarrhal disturbances in the upper air-passages.

In these cases we find that the superior maxillary bones are not only contracted, but are likewise elevated, abnormally increasing the depth and diminishing the diameter of the roof of the mouth. The vertical measurement of the osseous nares is naturally more or less affected by the encroachment of the elevated hard palate, and the nasal septum, as a consequence, is bent laterally, as exemplified in the diagram, Fig. 1, A representing the normal septum and maxillary arch, and B the abnormal.



A. B.

Fig. 1.

These plaster impressions, kindly presented to me by Dr. Eddy, nicely illustrate this peculiar palatine formation. They were selected from among thirty other plaster casts as the only two in which I could positively pronounce the existence of a chronic nasal catarrh. The doctor, on referring to the name of the subject, found that both belonged to the same individual—a patient he had referred to me several years before for a severe chronic coryza, and the only one out of the whole number of casts. On comparing this plaster impression, Fig. 2, with the normal palatine arch, you will discern certain well-defined differences. The distance between the alveolar ridges is much greater in the normal specimen. The transverse diameter of the abnormal specimen is not only smaller, but its surface is markedly irregular. The maxillary arch may be considerably higher than this normal specimen, and yet not constitute a pathological condition. No two maxillary arches are exactly alike, and some exhibit an elevation easily mistaken for a deformity. The important distinction to bear in mind is the abrupt elevation along the line of the median rhaphe. When such a condition is observed, we may at once look for, and, in my experience, invariably discover, a corresponding deviation of the septum. This condition, furthermore,

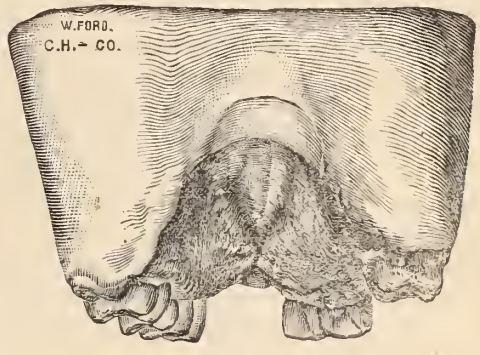


Fig. 2.

* See "Archives of Laryngology," 1882, vol. iii, p. 300.

† *Ibid.*, vol. ii, p. 147.

‡ *Ibid.*, vol. iii, p. 108.

is found associated with a chronic coryza. Indeed, I hold it to be possible in certain cases to diagnosticate the existence of a chronic nasal catarrh by the simple examination of the roof of the mouth, or, what amounts to the same thing, by inspecting an impression in wax or plaster, from any part of the world. After having ascertained the congenital character of this nasal abnormality, the next step was an endeavor to account for its existence. In tracing this peculiar formation to its hereditary origin, I was greatly assisted by instituting a comparative study of the external nose, and particularly the persistence of certain types in the same family.* By employing a similar method of reasoning to the internal configuration of the nares, I have been able to trace the peculiar conformation back to a common parental origin. This condition occurs as an hereditary manifestation with great constancy. Once the peculiar nasal type of the parents is recognized, its modifications in the children are easily determined.

It would appear that abnormal contraction of the nares is likely to be associated with intellectual enlargement of the skull in certain families, a fact which may serve to account for the tendency to phthisis attributed by some observers to severely studious or sedentary habits.

It is well known that a marked increase in the dimensions of the cranial dome is apt to be accompanied by a contraction of the osseous frame-work of the face. If it were convenient I might cite a number of interesting examples, carefully collected by me, to prove the correctness of this view.

Through Dr. L. J. B., referred to me by Dr. P. A. Morrow, my interest in the elevated arch and the septum of heredity received a fresh impulse.

Fig. 3 is a reproduction of the doctor's palatine profile. He creditably appreciated the significance of the high-pitched arch, and directed my attention to the peculiar formation of his own. The co-existing deviation of the septum was very well marked, and there were several other interesting features connected with this physician's condition.

I might mention, for instance, the unique occurrence, as far as I know, of a periodical perspiration over a circumscribed area, above the left malar prominence, and around the neighboring portion of the cheek.

There was an extensive *general* deviation of the septum to the left, and it was fair to presume that this peculiar perspiratory anomaly was due to prolonged intra-nasal pressure exerted by the deflected structure.

The prompt disappearance of this annoying symptom after removal of the offending tissues confirmed the correctness of this view. The doctor, although a life-long sufferer with nasal catarrh, was so much benefited by surgical treatment as to pronounce himself, in certain respects, a different man. Free nasal respiration through the left nostril was, for the first time in his life, made possible.

The following extract from his family history is of interest as regards the question of heredity: His father, a physician now deceased, was all his life-time annoyed by a persistent coryza and throat trouble. On comparing the doctor's photograph with an oil-painting of his father, a resemblance in respect to the shape of the nose and forehead is sufficiently well marked to challenge the attention of even a casual observer. Furthermore, I ascertained, from a member of the family, that his grandfather, also a physician, looked like his father and was afflicted with a catarrhal affection.

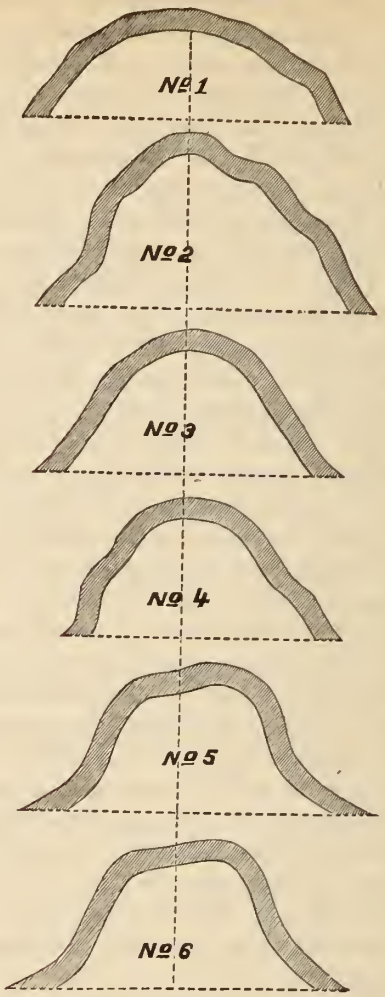

Fig. 3.

I have selected from my case-book a few life-sketches, which will aid me in explaining what I mean by hereditary deviation of the septum. This, Fig. 4, was copied from the life-sketch of a boy, aged fourteen, referred to me by Dr.

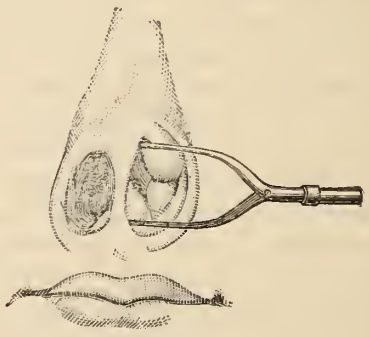

Fig. 4.

* "It is said by Ribot that, of all the features, the nose is the one which heredity preserves best."—"Hereditary Traits," Richard A. Proctor.

A. W. Berle, of New York, and the next drawing, Fig. 5, was taken from the father of the lad. The hard palates of both were markedly contracted and elevated. The father had bilateral deviation of the septum with life-long nasal catarrh, and the son was referred to me for relief from the same trouble.

A cross-section of the elevated and contracted hard palates is shown in Fig. 3, where No. 3 represents the father and No. 4 his son.

These tracings were obtained by taking a wax impression of the roof of the mouth, then reproducing the deformity in plaster of Paris, and dividing the casts thus obtained with a fine saw, in a transverse direction. The divided fragments were then simply laid upon a piece of paper and outlined.

You may be able to distinguish a slight resemblance in their shape, when compared with each other, this similarity being rendered more distinct by their dissimilarity with the other arches.

An idea of their abnormal divergence from the true type may be obtained by comparing the two arches with No. 1, taken from a plaster cast exhibiting an unusually flattened and expanded hard palate, and selected as an extreme illustration of the kind.

Returning to the sketches (Fig. 4) you observe the cartilage of the son's septum is deviated to the left as a localized nodular projection, almost on a level with the floor of the nose.

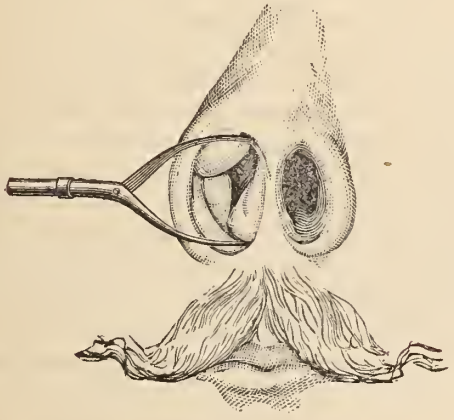

Fig. 5.

The father's septum (Fig. 5) was also thrown to the left, but, in the form of general deviation, situated superiorly in the nostril, the inferior-anterior edge of the septum being deflected into the right nostril in a manner similar to the son's.

It may be worth noting that when the lad was first brought to me I sought the hereditary origin of his deviated septum in the mother's nose, with a negative result; and yet, unwilling to be adjudged guilty of an erroneous conjecture, I persuaded the mother to induce her husband to visit me, and proved the correctness of my inferences as just described. The removal of the deviated cartilage from the boy's nostril was followed by an excellent result. This drawing (Fig. 6) shows the nose of a son aged twenty-two, and next to it (Fig. 7) that of the father. They are copied from life-sketches. You observe that both septa are *generally* deviated in the same direction. Both were severely afflicted with a life-long coryza.

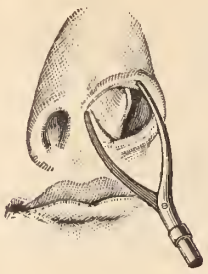

Fig. 6.

Fig. 7.

Fig. 3, Nos. 5 and 6, exhibit transverse tracings of the father's and son's hard palates in the order mentioned. The point of highest elevation, it will be observed, is toward the nostrils into which the septa were deflected. The father, an old man, had become reconciled to his lot in life, although the extremely harassing character of his complaint made me marvel at this decision.

His bitter experience had the happy effect of making him alive to his son's life-interests. Directing our attention again to the sketches (Figs. 6 and 7), you observe the cartilage of the septum is conspicuously inclined to the left in both father and son. The father's septum (Fig. 7) exhibits, however, a greater degree of deflection, the respiratory space being reduced to a useless slit.

You may be able to distinguish a similarity in the shape of the external nose. The father, although a sufferer for many years with bronchitis and asthma, might be considered, under the circumstances, tolerably well developed and preserved. The son, on the contrary, also complaining of lung trouble, was stunted in stature, emaciated in appearance, with a haggard face and an unhealthy skin.

I operated upon the young man, removing two antero-inferior turbinated hypertrophies, and shaving off the septum for the whole length of the triangular cartilage, excising also a small portion of the anterior border of the vomer. Fig. 8, taken from a life-sketch, exhibits the left

Fig. 8.

nostril after excision of the deviated structures. I employed my transfixion needles and écraseur for the removal of the redundant turbinated tissues, using my fenestrated cartilage forceps, tubular-spring forceps, and rongeur bone scissors for leveling the septum.

The subject of this illustration (Fig. 9) was afflicted

with, and cured by me of, an extensive osseo-cartilaginous deviation of the septum. The drawing was taken from a

Fig. 9.

life-sketch, and the history of this individual throws much light upon the origin and growth of the septum of heredity. You may catch my meaning when I inform you that I was enabled to correctly diagnosticate, or, more accurately speaking, infer, through this patient, the general condition of the nostrils and health of all his brothers, four in number, and his father. In this family the nasal asymmetry was very well marked, the septum in one instance being deviated to such an extent as to disturb the external symmetry of the nostril. All the young men seen by me, three in number, possessed the paternal nasal type and palatine arch in an exaggerated form. All have suffered with nasal catarrh dating far back in the memory of the family, and I am informed that the absent son, not yet examined by me, is severely afflicted with the same complaint. The patient, an engineer by profession and a very intelligent individual, referred to me by Dr. J. L. Corning, stated that a physician informed him that his condition was due to a scrofulous taint, probably inherited from his father. I failed to discover the slightest trace of scrofula in any of these individuals.

The cases I have just cited are not to be considered, as regards their immediate condition, phthisical in character; they have simply been submitted as excellent examples of the influence of heredity as a determining factor in the production of nasal disease, and as such must assist us in interpreting the same conditions when found in phthisis.

The testimony which I have just submitted, re-enforced by much more which I could, but can not now conveniently, offer, affords, to my manner of thinking, excellent proof of the intimate association of a high-pitched hard palate with a deviated septum, and their transmission from parent to child.

The relation of *traumatic deviation of the septum* to nasal catarrh and catarrhal phthisis is not so important as that of the hereditary variety; still it possesses many points of interest did time permit their consideration. Traumatic deviations of the septum, especially in those not predisposed to phthisis, are not likely to be followed by pulmonary tuberculosis. It should be borne in mind that the two conditions may be associated. The differentiation, however, as I shall have occasion to explain, is, as a rule, easily accomplished.

Although the cases of induced coryza just cited by me were of the hypertrophic variety, it should not be inferred that rhinitis atrophica may not be developed by the deviated septum.

Deviations determining the existence of atrophic coryza are *general* in character, and the dryness is evidently due to the excessive drain upon the mucous follicles resulting from the prolonged passage of air through a single nostril.

As an example of pulmonary phthisis following in the train of a rhinitis atrophica, I may be permitted, in an effort to make my meaning clearer, to precede my report of cases with a brief reference to a patient, aged thirty, treated by me at the University College Dispensary in the winter of 1882.* I found the nasal septum in this individual most extensively deflected, the deviation being osseo-cartilaginous in character. An atrophic rhinitis existed as a result of the nasal disease, both nasal chambers being inordinately enlarged through long-standing atrophic processes. Large and firm masses of muco-purulent matter clung to their smooth walls. These dry crusts were constantly detached and precipitated into the throat, irritating and inflaming the larynx. The patient was harassed and enfeebled by the unremitting efforts required to free his throat and larynx from these suffocating crusts. The atrophic processes had reached the pharynx, where, in the form of a pharyngitis sicca, it presented a dry patch, which obstructed the downward flow of the scanty nasal mucus, collecting it in the shape of sticky incrustations just behind the velum.

A laryngoscopic examination showed the true cords to be deeply injected and the contiguous structures inflamed by reason of the constant irritative action of the nasal incrustations which had found lodgment there.

The patient was extremely emaciated, weak, and miserable through the constant efforts required to free the throat from inspissated irritating discharges. There were night-sweats and the usual symptoms of advanced phthisis. An examination of his lungs, conducted by Dr. Moore, assistant to the Department of Medicine at the University Dispensary, and myself, revealed the existence of advanced destructive processes, as evidenced by the presence of cavities, a profusion of fine crepitant râles, and other familiar signs of the last stage of a rapidly progressing pulmonary phthisis. It was clear that the patient had reached a point where fatal prostration was imminent, and for an important reason we considered it best to advise him of his hopeless condition. Hoping to delay the fatal issue as much as possible, the patient found it convenient to accept the invitation of relatives in Florida, and so passed from under my observation.

The points of interest to us as regards this case, briefly summed up, are the history of a long-standing nasal catarrh and the manner in which it developed a pulmonary phthisis. That the nasal catarrh preceded the tubercular disease is proved by two features of the affection—namely, a deviated septum, osseo-cartilaginous in character, not associated with external nasal disfigurement, and therefore non-traumatic but hereditary, and a rhinitis atrophica.

Either of these pathological conditions would indicate the chronicity and persistency of the nasal catarrh, and

* See also No. I of illustrative cases.

therefore prove that they must have preceded the pulmonary disease; and in this, and in similar cases, we are afforded excellent evidence of the occurrence of the pulmonary lesion as a secondary complication to the catarrhal processes.

(*To be concluded.*)

Book Notices.

The Principles of Ventilation and Heating, and their Practical Application. By John S. Billings, M. D., LL. D. (Edin.), Surgeon, U. S. Army. New York: The Sanitary Engineer. 1884. Pp. 216. [Price, $3.]

Dr. Billings's book is a most scholarly exposition of the subject of which it treats. The author refers very modestly to his work in the opening sentence as if it were a short pamphlet which he had thrown off for the instruction of amateurs, but it is soon evident on turning over its pages that he enters into the subject in a thoroughly scientific and exhaustive manner. The book is divided into twelve chapters, the first three of which deal with the scientific aspect of the question, while the remaining chapters are devoted to the practical application of scientific facts. The subject of ventilation occupies most of the space. There are seventy-two illustrations, principally representing plans of public buildings and sanitary apparatus.

Dr. Billings's style is clear and pleasing, and his work is an extremely useful one to all who are interested in this branch of sanitary engineering.

The Middlesex Hospital. Reports of the Medical, Surgical, and Pathological Registrars, for the Year 1883. London: H. K. Lewis, 1885. Pp. 544.

This volume contains much interesting matter, although the method of tabulating the cases is, in our judgment, not the best. It is divided into a medical and surgical report. The former deals only with typhoid fever, diseases of the nervous system of special interest, and malignant growths; the latter with cancer of the uterus, breast, tongue and mouth, lower lip, rectum, miscellaneous cancers, rodent ulcer, sarcoma, non-malignant tumors, infectious diseases, strangulated hernia, and compound fracture. In each class the cases are arranged in a tabular form, which, although there is something in favor of such a method of registration, leads to much space being sacrificed, and makes difficult and unsatisfactory reading.

There is no general summary, and but a slight attempt at any practical deduction. The labor of preparing such a report must have been very great, while this arrangement detracts much from the value of the work. We trust that in a future volume the editors will do away with the strict tabular arrangement.

The History of a Legislative Shame.

Correspondence.

LETTER FROM CINCINNATI.

The Ohio Profession and the International Medical Congress.—Dr. Lane's Case.—Cincinnati Physicians as Artists.

Cincinnati, *August 31, 1885.*

Under date of August 20th, Dr. William Morrow Beach, president of the Ohio State Medical Society, issued a call for "a conference of the leading physicians" of the State, to be held at Columbus on the 27th inst., to take action relative to the International Medical Congress. The letter alludes to the present outlook and says that "some steps must be taken, promptly and energetically, to bring the existing factions into harmony." The president also says: "It has seemed to me the part of wisdom for Ohio, which is an important and pivotal State, to take the initiative." The object of the meeting was to "offer suggestions or give instructions to our State representative" in the enlarged committee for the guidance of his action at the New York meeting on the 3d prox. The letter concludes: "If you can not come, send a proxy, as this should be a thoroughly representative meeting. The following gentlemen, among others, have been especially invited to be present, although any others who are interested will be cordially welcomed." Then follow the names of thirty-six gentlemen,

among which occur those of all the physicians, or, at least, nearly all of those in Ohio who resigned from the new organization.

The wording of the call was certainly unfortunate, if the whole movement was not a *faux pas*. Those who had resigned surely could not be expected to participate in a meeting the object of which was to harmonize them with a faction from which, by their own acts, they had dissociated themselves, while the equivocal welcome promised to those not "especially invited" kept the mass of the profession away. At any rate, of the several thousand physicians in Ohio but enough attended the meeting to allow a maximum vote of twenty-three! Of those voting there were but twelve from outside of Columbus!

This "representative meeting," held in the hub city of the "pivotal State," proceeded to business by very properly dismissing the reporters of the secular press. A committee, consisting of Dr. Fowler, Dr. Franklin, Dr. Greenleaf, Dr. Baldwin, Dr. Larimore, and Dr. Vance, was appointed to draft resolutions. After an hour and a half a report was presented in purport as follows:

First.—That the Ohio delegate use his influence to harmonize existing difficulties, accept no resignations, but insist that all officers and committees perform their work toward arranging for the International Congress. [Carried.]

Second.—That geographical boundaries be not considered in making appointments of officers and committees, but that men of ability, no matter where resident, be made the appointees. [Carried.]

Third.—That no code questions be considered in the *organization* of the Congress. [Amended by striking out "organization" and inserting "membership," after which it was adopted —19 to 3.]

Fourth.—That the enlarged committee (of 46) at its New York meeting *reinstate* all those whom it had dropped from the list prepared by the original committee (of 8), and from the list as thus increased, and with such additions as they might see fit to make, *redistribute* the offices. [Lost, 10 to 13.]

It is now known that, were the vote on the last resolution to be taken over again, the result would be different, as its real purport was not comprehended by the meeting. I have it, *ex cathedra*, that the object of those framing the resolution and reporting it was that the men proposed by the old committee and to be now reinstated by the new committee should all be officers, but that their various offices should be determined by the enlarged committee, the idea being to admit the new-code men but to relegate them to the lowermost rooms; *i. e.*, to the "councils" of their respective sections. The word "reinstate" led the meeting to infer that the proposition was that the "reinstated" were to have their former "offices," which was not contemplated.

The net result of the meeting, so far as anything of importance is concerned, was, therefore, the passage of a resolution instructing the delegate from Ohio to vote for a proposition to allow the new-code men to come into the Congress as *members*. To what extent this result will tend "to bring the existing factions into harmony," particularly when viewed by the light of the inside facts which I have given, remains to be seen. But, small and far from "representative" as was the meeting, its conclusions were a slap in the face to the American Medical Association and a triumph to the new-code men. The repudiation of the "geographical-distribution" idea was an intimation to the National Association of its asininity; the recommendation that new-code men be admitted to "membership" in the International Congress conceded their importance to the scientific feature of that gathering; and when it was seriously proposed to capture them, even at the expense of Jesuitical methods, it was as much as saying, "They come high, but we must have them." At any rate, viewing the meeting only in the light of its action, it is to be taken as one of the evidences of "weakening" on the part of those who, in the main, have been in sympathy with the action taken at New Orleans.

Apropos of the International Congress imbroglio it may be stated that the deposing of Dr. Levi C. Lane, of California, from the vice-presidency of the Congress is exciting considerable comment in this State. Dr. Lane is a native of southwestern Ohio, and is to-day one of the conspicuous successes among the sons of the "Buckeye State." The product of the best educational methods, he is the typification of the "scholar in medicine"; and, the apostle of industry and thrift, he is, in both a scientific and pecuniary sense, an illustration of conspicuous success in his profession. That he should have been removed is deplorable; but that the committee should have permitted itself to be thus imposed upon is still more so. If the forty-six gentlemen comprising that committee are so ignorant of the true status of the great men of our profession, they are simply unfit for the duties devolving upon them.

Cincinnati, as your readers all know, has an extensive reputation as an art center; but the fact that several members of the medical profession have become quite accomplished artists, while not at all surprising, is yet not so generally known. One of our most accomplished *dilettanti* is Dr. Daniel S. Young, whose office and studio are crowded with treasures and curios that are the products of his artistic tastes. His efforts cover almost every department of art; oil and crayon pictures abound, while etchings are not rare; and wood-carving and sculpture in plaster are familiar pastimes. One of his most successful efforts —a *bas-relief* in plaster of the late Dr. George C. Blackman— adorns the walls of the library of the Cincinnati Hospital, while the rare museums of the Cuvier Club and of the Cincinnati Natural History Society are largely indebted to his skill as a taxidermist for many of their most interesting and valuable specimens. It may be proper to add that Dr. Young is a hard worker in his profession, and finds time for his art labors amid the exactions arising from his extensive private practice, from his duties as staff surgeon to the Cincinnati Hospital, and from his work as a clinical teacher of surgery. One of the most promising of our younger men, whether viewed as physician or artist, is Dr. W. Kincheloe Baker. He has achieved his celebrity as an artist chiefly through the rare superiority of his etchings. His work, particularly in this department, is far above the order of dilettanteism. Among his more recent productions is an etching of the late Dr. Samuel D. Gross—certainly one of the most striking likenesses and effective pictures it has ever been my pleasure to behold. Another of Dr. Baker's etchings is of the late Dr. William Judkins, *père;* that it, too, is a faithful picture is assured by the indorsement of the present owner of the plate, Dr. William Judkins, *fils*, and by those who were the compeers and colleagues of the distinguished pioneer. Dr. Reamy, an elegant subject for a picture, is another well-satisfied patron of Dr. Baker's art. Another of our physicians, Dr. William A. Rothacker, the editor of "Henke's Atlas," although not engaged in art production, is, however, professor of anatomy at the art school. In addition to these, the profession of Cincinnati affords a large number of art amateurs; but while writing of the amateurs within the profession it may not be amiss to mention one of the most promising, who is connected with it only by marriage—Mrs. J. H. Hazard, wife of the professor of physiology at the Cincinnati College of Medicine and Surgery. She has especially distinguished herself by executing in oil the elegant drawings with which her husband illustrates his lectures. It may be added that as an anatomist Mrs. Hazard has but few superiors, even in the profession.

NEW YORK, SATURDAY, SEPTEMBER 5, 1885.

THE HOBOKEN POISONING CASE.

THE distressing incident that happened in Hoboken a few days ago, whereby two young ladies lost their lives in consequence of an apothecary's error, should at least serve to intensify the vigilance with which pharmacists undoubtedly try to guard against mistakes of this nature. There is, unfortunately, nothing so rare in the occurrence, considered simply as an occurrence, as to make it specially monitory, but the exceptional character of the gentleman whose hard fate it has been to commit the error in this instance lends an unusual impressiveness to the calamity. The public is quite generally impressed with the idea that mistakes in the delivery of drugs to purchasers, or in the compounding of medicines ordered by prescription, necessarily imply either gross ignorance or inconceivable negligence, each of which shortcomings, brought into play under such circumstances, is held to amount to criminality. In conformity to this idea, the law not only holds persons whose mistakes of this sort are productive of fatal results as fit subjects for punishment, but aims to throw unusual safeguards about the practice of pharmacy by requiring of persons who seek to follow that pursuit ample evidence of their fitness for it.

In so far as the last-mentioned aim of the law is concerned, its wisdom is unquestionable, but its adequacy to the purpose is seen to be very imperfect when we reflect that, in the instance which calls forth these remarks, so commonplace an error as that of dispensing morphine instead of quinine was committed by a gentleman who for years had stood among the foremost in his profession. Although his place of business was in Hoboken, where the ordinary working of the laws of trade would have brought him only a patronage limited to the people of his immediate neighborhood, he had become widely known to physicians for his skill and carefulness as a pharmacist, as well as for the trustworthy character of certain medicinal preparations and surgical appliances that were his own special productions. Mr. Am Ende has long occupied a most honorable position in the estimation of the medical profession. Certainly it was no lack of capability that led him into his fatal error. It is said that his mistake is only to be accounted for by the fact that persons who happened to be in his shop at the time persisted in talking to him when he was engaged in putting up the prescription. It is not at all unlikely that this is the true explanation, and, considering the aggravating persistency with which men engaged in delicate and responsible work are distracted and worried by chance visitors, the wonder is that accidents involving grave consequences do not happen oftener.

Perhaps it would hardly do for the law to relax its hold upon persons who make fatal mistakes in the practice of pharmacy, but leniency, both on the part of the courts and on the part of the community, is certainly called for in cases where, as in the present instance, the lapse seems to be of a sort that no man could be sure of being able to guard against with anything like certainty. It is said that the father of the young ladies who lost their lives has sent a message of sympathy to Mr. Am Ende, and has even sent prescriptions to his shop since the fatal occurrence. We trust that this is true, for it would go far to allay a sense of grief that must be well-nigh unendurable. At all events, we are glad to believe that it is with no approach to vindictiveness that Mr. Am Ende is thought of by the better portion of the community.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 1, 1885:

DISEASES.	Week ending Aug. 25.		Week ending Sept. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	0	1
Typhoid fever	29	10	34	3
Scarlet fever	14	4	13	2
Cerebro-spinal meningitis	3	1	2	1
Measles	12	6	9	1
Diphtheria	31	17	21	11

The Health of the State of New York.—By the "Monthly Bulletin of the New York State Board of Health" for July we learn that the total reported mortality for the month was 9,318, the percentage among infants being 54·4. The proportion of deaths from zymotic diseases was 401·37 in each thousand, and that of deaths from diarrhœal diseases 320.

The International Medical Congress.—We copy the following from the "Louisville Medical News":

"*Charleston Physicians and the New Organization.*—The undersigned, for reasons connected with the changed circumstances in the organization of the proposed International Congress, since their appointment in the several sections, hereby respectfully withdraw their names.

"MIDDLETON MICHEL,
"F. PEYRE PORCHER,
"FRANCIS L. PARKER.

"*Chicago Physicians and the New Organization of the Congress.*—Believing that the American Medical Association, at its late meeting in New Orleans, took such action with reference to its committee, appointed one year before, to unite, arrange for, and organize the Ninth International Medical Congress, as to nullify in part the work performed by said committee, thereby jeopardizing the success of the proposed Congress and putting the medical profession of this country in a false and unfavorable light, the undersigned disapprove of this action of the association, and decline to serve in the positions to which they have been appointed in the Congress as at present organized.

"A. REEVES JACKSON, N. SENN,
"HENRY M. LYMAN, CHARLES T. PARKER.
"JAMES NEVINS HYDE,

"*Other Resignations from the New Organization.*—We are informed that Dr. Edwin M. Snow, of Providence, has declined the vice-presidency of the Section of Collective Investigation, Nomenclature, and Vital Statistics, and that Dr. D. Bryson Delavan, of New York, has declined the secretaryship of the Section of Laryngology.

"Dr. Thomas F. Wood, of Wilmington, N. C., has declined to serve on the Council of the Section of Practical and Experimental Therapeutics; likewise Drs. J. Rufus Tryon, U. S. N., and Alfred A. Woodhull, U. S. A., on the Council of the Section of Military and Naval Surgery and Medicine, and Dr. Christian Fenger on the Council of the Section of Pathology."

Editorially, the same journal says:

"The American Medical Association's new Committee on Rules and Preliminary Organization of the International Medical Congress of 1887 will meet by special call for the transaction of important business in New York on the 3d of September.

"The importance of this meeting can not be overstated, since it involves nothing less than the fate of the Congress and the good name of American medicine abroad. For, in spite of the large boasting of the new committee's supporters, that the recent numerous withdrawals of eminent men from among its appointees would not make against the successful meeting and working of the Congress, it is certain that the wise and far-seeing of the committee must own a serious loss of strength, and perceive that, as it is now proposed to be organized, the Congress will be a sorry failure, if indeed it be not kept from coming to this country.

"It is time to call a halt to controversy. Let the attending physicians take further counsel and ascertain if there be any sign of life in this object of deep professional solicitude. If so much as a spark remain, let it be duly fanned and fed; but if, as seems more probable, decomposition is already far advanced, the sooner the remains are given decent burial and the premises disinfected the better for those whose blundering treatment killed their precious charge."

A Proposed International Dental Congress.—On account of the dropping of the Section in Oral and Dental Surgery from the organization of the Ninth International Medical Congress, as at present laid out, the project has been broached among our dentists of holding an International Dental Congress in Washington at the same time with the meeting of the Medical Congress. The "Independent Practitioner" deprecates the scheme. It says:

"We can not, without serious loss of dignity, sue to the present General Committee of the Congress for reinstatement as a section, after being once dropped by them under humiliating circumstances. Nor should we wish such reinstatement, in the face of a probable failure.

"Should the section not be re-established, it would, to our mind, be a very questionable act to call an International Dental Congress to meet at the same time, for the following reasons: We probably could not make of it a success. We should be in a very undignified position, as a kind of hanger-on to a Congress from which we had been rudely repulsed. We could have no connection with the Congress, any more than would a meeting of photographers, or commercial drummers, or spindle-shanked bicyclists. We should not even be a part of the tail to the medical kite, for we should have no connection with it. We could not secure foreign attendance, for the dentists of Europe would valne their dignity too much to attend such a meeting, even were we so forgetful of our own as to invite them.

"The only thing for dentists to do is to pursue the even tenor of their way, doing what they can for the proper reconstruction of the General Committee of the Congress. If this be secured, and the meeting promises to be a success, we shall doubtless be invited to take a part in it. If not, we are lucky to be out of it, for we should present but a sorry spectacle should we labor either for our own re-establishment in the Congress under the present *régime*, or for the organization of a separate International Dental Congress, and, when we were fully committed, find to our chagrin that an event, which now seems extremely probable, had occurred, and the acceptance of the invitation to meet in America had been withdrawn and the meeting called for Berlin."

The American Dermatological Association elected officers as follows at its recent annual meeting: Dr. Edward Wigglesworth, of Boston, president; Dr. I. E. Atkinson, of Baltimore, and Dr. A. R. Robinson, of New York, vice-presidents; Dr. G. H. Tilden, of Boston, secretary; and Dr. H. W. Stelwagon, of Philadelphia, treasurer.

The meeting held in Greenwich last week was of a character to show the continued vitality of the association, but yet the discussions and the papers read were such as to appeal more directly and forcibly to the general practitioner than is apt to be the case with the proceedings of special societies. The attendance, too, was fairly representative of the different quarters of the country, and included nearly all of our better-known dermatologists. Dermatology, as our readers are well aware, is one of the departments of medicine in which America has been able to make a creditable showing, and hence the career of this association is of special interest to the profession.

The American Rhinological Association will hold its third annual meeting at Lexington, Ky., on Tuesday, October 6th. Papers and discussions will be devoted exclusively to the diseases of the nasal passages and their consequences. The following is the list of officers for 1885:

President, Dr. P. W. Logan, Knoxville, Tenn.; First Vice-President, Dr. A. De Vilbiss, Toledo, Ohio; Second Vice-President, Dr. J. A. Stucky, Lexington, Ky.; Recording Secretary, Dr. C. A. S. Sims, St. Joseph, Mo.; Librarian, Dr. R. N. Gordon, Springfield, Ill.; Council, Dr. J. G. Carpenter, Stanford, Ky.; Dr. H. Jerard, East Lynne, Mo.; Dr. H. Christopher, St. Joseph, Mo.; and Dr. E. F. Henderson, Los Angeles, Cal.

Full information may be obtained from any of the foregoing officers of the association.

The Indiana State Medical Society.—At the last annual meeting of the society an unpleasant occurrence took place, as some of our readers may remember, being no less than the charge, brought against a gentleman who read an account of a case in which he trephined the vertebral column, that an operation reported as trephining really consisted only in "scraping of the spinous processes." Dr. C. B. Stemen, the author of the paper, who is also the editor of the "Fort Wayne Journal of the Medical Sciences," now gives in that journal evidence which certainly seems to show conclusively that the accusation brought against him at the meeting was unjust.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 22, 1885, to August 29, 1885:*

Cronkhite, H. M., Captain and Assistant Surgeon. Relieved from duty at Fort Reno, Indian Territory, and assigned to duty as post surgeon, Fort Hays, Kansas. S. O. 129, Department of the Missouri, August 26, 1885.

Powell, J. L., Captain and Assistant Surgeon. Relieved from temporary duty at Fort Leavenworth, Kansas, and assigned to duty as post surgeon at Fort Lyon, Colorado. S. O. 128, Department of the Missouri, August 25, 1885.

Ebert, R. G., Captain and Assistant Surgeon. Assigned to temporary duty with United States troops at Riverside Park, New York. S. O. 179, Department of the East, August 24, 1885.

Kane, John J., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect when his services can be spared. S. O. 195, A. G. O., August 26, 1885.

STEPHENSON, WILLIAM, First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect September 1, 1885 (Fort Niobrara, Nebraska). S. O. 79, Department of the Platte, August 20, 1885.

MCCAW, W. D., First Lieutenant and Assistant Surgeon. Assigned to temporary duty at the camp of the troops near Kiowa, Kansas. S. O. 128, Department of the Missouri, August 25, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the week ending August 29, 1885.*

JONES, WILLIAM H., Surgeon. Detached from the Wachusett, and waiting orders.

Society Meetings for the Coming Week:

MONDAY, *September 7th:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

TUESDAY, *September 8th:* New York Medical Union (private); Medical Societies of the Counties of Rensselaer and Chemung (Elmira), N. Y.; Newark (private) and Trenton (private), N. J., Medical Associations.

WEDNESDAY, *September 9th:* New York Pathological Society; American Microscopical Society of the City of New York; Medico-Legal Society; Medical Societies of the Counties of Cayuga and Montgomery, N. Y.; Philadelphia County Medical Society; Worcester District, Mass., Medical Society (Worcester).

THURSDAY, *September 10th:* Harlem Medical Association of the City of New York; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, *September 11th:* Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.

Proceedings of Societies.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Ninth Annual Meeting, held at Greenwich, Conn., Wednesday, Thursday, and Friday, August 26, 27, and 28, 1885.

The President, Dr. W. A. HARDAWAY, of St. Louis, in the Chair.

Wednesday's Proceedings.

A Case of Tuberculo-ulcerative Syphilide of Hereditary Origin was the title of the first paper, by Dr. J. E. GRAHAM, of Toronto. The patient was a girl twenty years of age. The skin of the forearm presented elevations and depressions, and in places it was covered with thin scales. For three or four inches above the elbow the arm was atrophied and covered with cicatricial tissue. At the upper border of the cicatricial tissue there was an ulcer three fourths of an inch wide, which encircled the arm. Above this there was sound tissue. No nodules were present. The left clavicle presented about its middle a swelling and an ulceration of about the size of a silver dollar. This was the result of a blow. There was no copper-colored appearance. Investigation of the family history showed that the mother was apparently healthy. The father died from pneumonia when the patient was eighteen months old. It was subsequently learned that he had also had syphilitic ulceration of the throat. The treatment consisted in the local application of a mild mercurial ointment and the internal use of bichloride of mercury and iodide of potassium. The condition steadily improved, and in the course of six or eight weeks the ulceration had healed. The patient at that time passed from observation.

The speaker referred to the difficulties of diagnosis in this case, as there was a complete absence of specific history, the facts in regard to the father not being learned for some time after the case had been under treatment. There was no history of any previous evidence of hereditary syphilis, but, taking all the facts into consideration, there could be no doubt as to the correctness of the diagnosis. Photographs showing the condition were exhibited.

Dr. R. W. TAYLOR, of New York, said it was now generally conceded that syphilis could be communicated to the child without infection of the mother, and he believed that he had been the first one in America to call attention to this fact. He had seen this a number of times. The author had stated that he could obtain no history of early manifestations of hereditary syphilis. This was not uncommon, but he believed that there was usually some indication of specific taint, although it might be so slight as not to excite notice.

Dr. C. HEITZMAN, of New York, said that every one had seen cases similar to the one reported. He had seen cases in which he was unable to determine the nature of the affection at first sight. The diagnosis lay between syphilis and scrofula.

Dr. F. B. GREENOUGH, of Boston, said that within the past two months he had seen a woman who had lost three children in succession from hereditary syphilis, yet she was strong and apparently perfectly healthy, and had never shown any signs of syphilis. This woman had been under observation for six or seven years.

Dr. L. A. DUHRING, of Philadelphia, said there were certain cases in which it was almost impossible to express a positive diagnosis at first. The result of treatment in causing a rapid cure in the case described would certainly incline him to the opinion that this was a case of syphilitic disease.

Dr. J. N. HYDE, of Chicago, had seen cases which had convinced him that, while it was not the rule, still occasionally syphilitic children were born without, so far as observation could be made, any evidence of syphilis being detected in the mother. So far as the general health was concerned, he could not say that he had seen vigorous, healthy women the mothers of syphilitic children. The women were usually pallid and weak, although there might be no symptoms which could be ascribed to syphilis. He saw inherited syphilis in infants constantly, but he had never seen it manifesting itself for the first time in advanced years, or, if he had, he had failed to make the proper diagnosis. The more he saw of syphilis, the more was he satisfied that in its origin heredity did not amount to very much. The accidental cases of syphilis were very common. He had seen the initial lesion of syphilis on the head of a penis where it was unquestionably due to inoculation from the finger of the surgeon in catheterization. He had no doubt that the case described was one of syphilitic trouble, and, as Dr. Duhring had said, the result of treatment unquestionably pointed in that direction. There were no cases which yielded so readily as old cases of untreated syphilis. As to pronouncing it a case of hereditary syphilis, his experience would not permit him to do so.

The PRESIDENT thought that it was unwise to base our diagnosis on the results of internal treatment. If a patient got well

under anti-syphilitic treatment, it did not prove that the affection was specific. Local treatment was often all that was necessary.

Dr. Taylor entirely disagreed with Dr. Hyde as to the condition of the mothers of syphilitic children. He had observed them to be in robust health.

Clinical Notes on Psoriasis.—Dr. Greenough read a paper founded on the records of 394 cases of psoriasis. This number occurred in about 15,000 cases of skin diseases examined, and represented about two and one half per cent. Many of the patients were first attacked between the ages of ten and forty years. In 97 cases the speaker had been able to get reliable evidence in regard to the family history. In 31 cases psoriasis had existed in a near relative, but in 66 cases the patients felt sure that the disease had existed in no other member of the family.

Well-marked cases were readily diagnosticated, but in some cases there was considerable difficulty in making the diagnosis. The disease was most frequently confounded with some form of eruption resulting from constitutional syphilis. When psoriasis affected the scalp its appearance was often similar to that of secondary syphilis. In psoriasis, however, the patch consisted simply of epithelial cells, and there was no hyperæmia connected with it. In the syphilitic eruption the crust contained other elements than epithelial cells, and, on removing the crust, spots of moisture would be detected. A characteristic symptom of psoriasis of the scalp was a band of hyperæmia, about three fourths of an inch wide, extending around the forehead, contiguous to the hair. This was a point of value in the diagnosis between eczema capitis and psoriasis. In the former affection this band was wanting. In eczema, also, evidences of dried serum or pus would be found. Psoriasis was not accompanied with enlargement of the posterior cervical glands like eczema. The diagnosis from favus was made by the age of the patient, the evidences of destruction of the hair follicles in favus, and the microscopical examination. On the general integument, syphilides were most apt to resemble psoriasis. The regions on which the eruption appear was important. The syphilides were apt to affect the flexor surfaces, while psoriasis affected more commonly the extensor aspects. Psoriasis began as a minute point of hyperæmia, which might last for several days. In the macular syphilide a crop of macules appeared within twenty-four or forty-eight hours. When the eruption faded there was in syphilis a decided pigmentary change. In some cases of psoriasis there was severe itching leading to scratching of the skin, and, as a result, scabs and crusts made their appearance, but here the cause of the condition was readily recognized. The amount of pruritus complained of in psoriasis varied, but it was rarely a prominent symptom, although in exceptional cases it is very severe. In regard to treatment there was no specific. What would benefit one patient might make another worse. In his experience, tarry preparations, especially the oil of cade, had been most efficacious. Great comfort might be afforded by the use of emollients. Cod-liver oil was one of the best applications. Cod-liver oil and oil of cade (equal parts) was a common prescription. Chrysarobin was a powerful remedy, but had the disadvantage of destroying the clothing. On the face and scalp it was apt to produce dermatitis. Even after apparent recovery there was great danger of relapse.

Dr. Duhring said that the reader had not alluded to the difficulty sometimes experienced in diagnosticating seborrhœa capitis from psoriasis. He had found considerable trouble in the diagnosis, particularly in young girls. In these cases the eruption was confined to the scalp.

Dr. A. R. Robinson, of New York, said that in the diagnosis of favus and psoriasis there was usually no difficulty. He did not agree with the author in regard to one of his points of diagnosis. In the early stage we should not find moisture when the crust was removed. There was a shiny appearance. It was only in advanced stages that ulceration was present. He considered it primarily an affection of the rete mucosum. While it was true that psoriasis often disappeared without producing pigmentation, there might be discoloration found on the lower extremities, particularly where there was a varicose condition of the veins.

Dr. J. C. White, of Boston, agreed with the previous speakers in regard to the difficulty of diagnosticating between psoriasis of the scalp and seborrhœa. In some cases the diagnosis could not be made for months. In all parts of the body pigmentation might follow psoriasis, but never over large areas.

Dr. R. B. Morison, of Baltimore, saw a great many cases of psoriasis, but could only recall one or two cases of psoriasis in the negro. In such cases there was a loss of pigment.

Dr. G. H. Fox, of New York, thought too much stress was laid on the general rule that psoriasis occurred most frequently on the extensor surfaces, the knees and the elbows. It was a notable fact that in general psoriasis the vicinity of the knee and elbow escaped. Many cases of psoriasis occurred in weakly subjects, while, on the other hand, many cases of eczema appeared in robust persons. In every individual case, the better the patient's health the less likely was he to suffer from a recurrence of the affection. He had been very successful in the treatment of psoriasis, and in its management he adopted the teaching of the late Tilbury Fox, who laid stress on the point that in psoriasis, as in other inflammatory affections of the skin and also in lupus, the first thing to do was to lessen the congestion of the skin. The speaker did this by restricting the diet, and ordering fruits and vegetables. Tea, coffee, tobacco, and stimulants of all kinds were to be cut off. By so doing, more would be accomplished than was obtained by using arsenic and local applications at the start. In regard to local remedies, he never used tar in the treatment of psoriasis. With the application of chrysarobin made at the proper time, there was no necessity for the use of tar. He had seen many cases in which this drug did no good, but this was because the application was made when the patches of psoriasis were in a congested condition. If the acute congestion was lessened, chrysarobin will produce beneficial results.

Dr. C. Heitzman, of New York, thought that one of the most important points after making the diagnosis was to decide as to the acuteness or chronicity of the affection. If it was acute, local applications were to be avoided. If the case was chronic, chrysarobin might be used with advantage at least temporarily. It was not a cure. He agreed with Dr. Fox that restriction of the diet was important for the purpose of lessening the congestion. Tar could not be dispensed with. Chrysarobin remedied the disease for a time, but in a few months it returned. There was nothing like tar to prevent the recurrence. No mention had been made of pyrogallic acid, which did good in some cases. There were, however, some cases which could not be treated successfully with any remedies; the disease would steadily grow worse.

The President believed that in psoriasis we had a disease situated in the skin itself. It is frequently hereditary. The same sort of skin might be transmitted, just as a certain color of the hair or of the eye might be transmitted, and then any exciting cause might develop the psoriasis. He had seen psoriasis follow eczema. It was not unlikely that in seborrhœa of the scalp there might be the development of psoriasis. Internal causes might produce it. He had seen the excessive use of oatmeal produce typical psoriasis. In the treatment of psoriasis

it was important to regulate the diet. He cut off meats, and aided digestion in all possible ways. As a local application, chrysarobin with salicylic acid was very useful in chronic cases. Arsenic was useful on account of its action on the skin. This treatment might be followed by the application of sulphur ointment. In psoriasis of the scalp sulphur was quite an efficient remedy.

Dr. GREENOUGH had not intended to cover the entire subject of psoriasis in my paper. The omission of a consideration of seborrhœa was an oversight. In regard to pigmentation he had referred especially to those cases of psoriasis of the trunk which were most apt to be confounded with syphilides.

Cases of Angioma Pigmentosum et Atrophicum.—Dr. WHITE reported two cases. The first patient was a young man, seventeen years old, a Russian Pole. Freckles appeared on his face before he was two years of age. These increased in number until the age of six. When the telangiectatic condition first appeared was not noted. When seen, the patient was well developed and apparently in good health. He had, however, grown slowly, and was now no larger than a boy of twelve. The hair of the head was abundant and intensely black. The eyes were also black. The forehead and lower portion of the face were of a dark-brown color, and, on close inspection, small spots of a darker color were seen. The whole trunk was as dark as the skin of a dark Spaniard. The scrotum was very black, and the penis and glans presented dark spots. The arms and hands were thickly spattered. The legs were also affected. On the right thigh there was one spot of dark color covered with rather long hair. The mucous membrane of the mouth and pharynx was free from melanosis. On the right side of the face, occupying one half the surface, was a sharply defined area of white cicatricial-looking skin. Similar areas were seen on the other cheek, on the forehead, and about the mouth. A few white spots were seen on other portions of the body. The sensibility of the affected areas was decidedly lessened. Over parts of the face there were bright-red spots, varying in size from that of a pin's head to that of a pea. They were most noticeable in the atrophied portions. Within the lids there were two angiomatous new growths. Several vascular twigs were also seen on the face. A few red points were found on the general surface.

The second case was that of a brother of the first patient, aged three years, born in New York. When he was eighteen months old, little colored freckles were noticed on the face. Since then the condition had been developing. His hair was dark brown and his eyes were black. The face was covered with numerous dark-brown freckles. The spots were so close together that at a little distance the skin had a uniform color. In some places the spots were slightly elevated. The backs of the hands were covered with dark-brown spots; elsewhere the skin was clear. There were no leucodermic spots and no angiomatous conditions.

From a study of these cases, he concluded that in the beginning the development of these spots could not be distinguished from that of ordinary freckles. Gradually the spots multiplied until they involved a considerable portion of the skin. It was probable that several years might elapse without other manifestation of the disease. The telangiectatic condition was probably secondary. In the first case it was most developed in the atrophic portion. It was probable that in this case there would be hypertrophy of the epithelium and final transformation into epithelioma. This had been the result in the thirty-three cases which had been reported.

The Relations of Lupus Vulgaris to Tuberculosis.—Dr. HYDE read a paper in which the following clinical facts were cited in support of the view that lupus vulgaris was not the result, as had long been taught, of tuberculosis or other systemic diathesis, but was the product of a local infection by bacilli, entirely unassociated with any constitutional evidence of diathesis or predisposition: 1. The unimpeachable character of the family record in by far the larger number of cases of lupus vulgaris. 2. The fact that the disease was in its inception a disorder of the period of childhood, when for the most part the habits of the child were favorable to infection. 3. The several sites of predilection were those most favorable to such infection. 4. The failure of the disease to spread by inheritance. 5. The remarkable tendency of lupus vulgaris to cutaneous limitation.

The Treatment of Lupus by Parasiticides.—Dr. WHITE reviewed briefly the evidence in favor of the parasitic nature of the affection. All previous plans of treatment which had proved most successful were those which would have the effect of destroying any parasite which might be present. A number of cases were then reported in which the local use of corrosive sublimate, in the strength of two grains to the ounce of water or unguent, had been used with beneficial results. The ointment was especially recommended. It had been rarely necessary to prolong the treatment over two months. As regarded the permanency of the cure the author was unable to speak, as the experiments had been continued for only eighteen months.

Dr. S. SHERWELL, of Brooklyn, would express his profound disbelief in the parasitic nature of the disease, and he did not know that the theories of Koch had been entirely proved.

Dr. HYDE said that at the last meeting Dr. Taylor had suggested the use of a solution of corrosive sublimate in tincture of benzoin. He had used this in cases of lupus and in cases of infecting chancre. It made an excellent application.

The Treatment of Port-wine Mark by Electrolysis.—The PRESIDENT read a paper with this title. In the treatment of this affection the object was to excite sufficient inflammation to cause occlusion of the vessels. Electrolysis seemed to be the most convenient way of doing this. At first the author had used a bundle of needles, but he now employed only the single needle. It was important to allow a period of some weeks to elapse between the applications. The histories of three cases were given in which this method had been employed.

Dr. WIGGLESWORTH, of Boston, had seen good results from cutting the vessels in two places and using a preparation of iron, thus closing up the dilated vessels.

Dr. FOX thought that better results could be obtained by electrolysis than by other measures, but it did not remove the trouble entirely. He had used the treatment with puncture and carbolic acid with fair results. He had sometimes passed the electrolytic needle deeply, endeavoring to strike the artery of supply, and sometimes had produced a decided effect.

Dr. LE GRAND N. DENSLOW, of Minneapolis, had recently seen a case of port-wine mark on the labia majora of an infant. This had ulcerated when the child was brought to him. As a temporary measure, he applied the liquor gutta-perchæ. In two days, without other treatment, the whole mark sloughed out, leaving nothing but a simple ulcer, which completely healed in the course of three weeks.

The PRESIDENT thought that the advantage of electrolysis was that it was manageable. A practical point might be referred to, and that was, if after the operation the part was frequently mopped with hot water, the inflammatory disturbance would be greatly lessened.

Remarks on a Moot Point in the Ætiology of Psoriasis.—Dr. SHERWELL read a paper with this title. He had been struck by the great diversity of opinion in regard to the general health of those affected with psoriasis, and, in order to arrive at something like a consensus of opinion on the subject, he had

referred to the writings of most of the authorities in dermatological matters. Brief extracts from various writers were then given. The evidence thus obtained strengthened the author's opinion that the patients with psoriasis were generally in good health. He thought that the theory of Piffard, who believed that the rhenmic diathesis was a great exciting cause of psoriasis, was the most rational theory that had been advanced.

(*To be concluded.*)

NEW YORK SOCIETY OF GERMAN PHYSICIANS.

Meeting of June 22, 1883.

Dr. B. Scharlau, and afterward Dr. I. Adler, in the Chair.

Ulcerated Gumma of the Sternum.—Dr. Hermann G. Klotz presented a man, sixty years old, whom he had treated at the German Dispensary. Three weeks ago he hurt his chest by striking against a hard object. Soon after he noticed a hard swelling which developed at the seat of the injury and finally ulcerated, but never gave him any pain. The nates and thighs exhibited pigmented scars, but there were no swollen glands. Dr. Klotz considered the swelling to be an ulcerated gnmma.

Kelotomy combined with the Radical Operation for Inguinal Hernia.—Dr. I. Adler presented a man, twenty-three years old, on whom he had performed this operation at the German Hospital four weeks ago. The patient had been afflicted with an irreducible hernia ever since he could remember, but had never worn a truss. When the doctor first saw him his abdomen was tense and painful, and he suffered from hiccough, nausea, and vomiting. His bowels had not moved for four days in spite of some homœopathic medicine prescribed for him by an irregular practitioner. The hernial protrusion gave a dull percussion sound. Dr. Adler at once proceeded to perform kelotomy. On opening the hernial sac, it was found to contain omentum which was firmly adherent to the hernial sac in many places, and a small, dark-red knuckle of intestine. The whole inguinal canal was laid open, and the internal ring was freely incised, whereupon the strangulated portion of intestine slipped back into the abdominal cavity. The adherent portions of the omentum were ligated and cut through with the thermo-cautery. The operation was supplemented by the radical procedure for hernia—viz., the stitching of the internal ring, which was done with stout catgut. The dressing was changed on the fourth day, and he was discharged at the end of two weeks.

Hæmorrhage following Abortion.—Dr. J. Boldt exhibited an ovum of the fourth week of gestation. The hæmorrhage occasioned by the miscarriage lasted about two weeks and was stopped only by scraping the uterine cavity.

Tetanus following Abortion.—Dr. Henry Wald reported the case of a woman, thirty-six years old, who had a miscarriage in consequence of excessive exertion, and in whom lockjaw set in three days afterward. Treatment was of no avail, and she died at the end of three days of suffering. At the time of death her temperature was 106° F.

Dr. I. Adler remarked that he had once tried nerve-stretching in a case of tetanus caused by a gunshot wound of the thumb, but without success.

Prolonged High Temperature.—Dr. A. Seibert reported the case of a baby, four months old, which he had treated for gastritis, and which for eighteen consecutive days almost uninterruptedly had a temperature of over 106°. The child recovered.

Tetany.—Dr. J. Rudisch related the case of a child, four years old, who at the time of the meeting was convalescing from an attack of tetany supposed to have been caused by taking cold while sleeping near an open window. The attack began with a severe headache, which was aggravated every time the little patient took nourishment. On the fourth day mastication and deglutition became difficult, and the usual symptoms of tetany were ushered in. Warm baths were at first employed, but they appeared to aggravate the convulsions; neither did salicylic acid produce any amelioration. The patient was then put on chloral hydrate and bromide of potassium, and the occasional use of amyl nitrite.

Operation for Empyema.—Dr. A. Caillé reported a successful operation of this kind which he had performed in a child fourteen months old. He employed Labarraque's solution for washing out the pleural cavity. Six weeks after the operation the little one had gained three pounds.

Meeting of September 28, 1883.

Dr. B. Scharlau in the Chair.

Dr. J. Boldt introduced a man, thirty-two years old, on whom Prof. Langenbeck, of Berlin, had performed exsection of the left elbow joint in the year 1876, resulting in a perfectly useful limb.

Perforation of the Lower Canaliculus due to Syphilis.—Dr. A. Schapringer presented a married woman, aged twenty-six years, with a perforation of the left lower lachrymal canaliculus, the result of ulceration of a tubercular syphilide which had occupied the region of the inner canthus. The patient having been put through a course of iodide of potassium, the syphilitic nodule itself had disappeared at the time she was shown to the society. The slit-shaped perforation involved the inner or nasal half of the lower canaliculus, transforming it into a furrow, while the outer or temporal half, including the lower punctum lacrymale, was normal. Through the slit-shaped opening No. 6 of Bowman's probes could be introduced into the lachrymal duct. There were also several small perforations in the soft palate. Dr. Schapringer had not been able to find a single case of perforation of a lachrymal canaliculus caused by syphilis recorded in literature.

Gonorrhœal Tenosynovitis.—Dr. A. G. Gerster reported the case of a young man who, during the course of the second week of his first gonorrhœa, was attacked by inflammation, followed by suppuration, of the tendon sheaths of the flexors of the middle finger and of the tibialis anticus. The abscesses formed were incised and washed out with a strong solution of corrosive sublimate. The wound healed in four weeks. Dr. Gerster considered this to be a case of metastatic gonorrhœal synovitis.

Dr. H. Knapp said, in answer to a question from the chairman, that the existence of a metastatic form of iritis due to gonorrhœa was established beyond any doubt, though it did not occur frequently. Whenever a patient suffering from iritis complained to him about pains in the knee, he always diagnosticated the presence of gonorrhœa, and had as yet never made a mistake.

Dr. I. P. Oberndorfer expressed doubts as to the existence of a causal relationship between gonorrhœa and rheumatism, and believed that the combination of the two diseases was purely accidental.

Dr. Gerster had seen about thirty cases of articular rheumatism following recent gonorrhœa or mechanical irritation of the inflamed mucous membrane of the urethra, and was convinced that the latter was the cause of the former. He had had repeated experience of the fact that the passing of a sound was followed either by inflammation of a joint, or by an exacerbation of an existing inflammation. These inflammations, as a rule, were very stubborn to treatment. In three cases in which

he had occasion to aspirate he found that the joints contained serum mixed with a small quantity of pus. A number of cases of gonorrhœal rheumatism turned into the tuberculous or fungoid form of arthritis. Dr. Gerster once had to perform partial exsection of a knee joint affected in this way. Ankylosis was often the result of this form of joint disease. In the treatment of gonorrhœal rheumatism, not only the original trouble should receive attention, but also the joints affected should have the benefit of special surgical care.

Dr. J. Rudisch remarked that the term "gonorrhœal rheumatism" ought to be discarded, because it was apt to be misleading in regard to therapeutics. Salicylic acid was never of any benefit in this disease. He had observed that the continued treatment of the urethral affection by injections always aggravated the joint trouble. He recommended the administration of iodide of potassium, to put the joint in splints, and not to meddle with the urethra at all.

Dr. Oberndorfer said that, if it was true that the suppression of the gonorrhœal secretion by local applications was apt to start or to aggravate joint inflammation, this fact was an argument against the view that the joint disease was due to gonorrhœal infection, because a cessation of the gonorrhœal flux could only be brought about by killing the micrococcus which caused it, and, if this was done, then the micrococcus, being dead, could not possibly cause any metastasis. He also thought that, if the arthritis was caused by the *Diplococcus gonorrhœæ*, the effusion into the joint would invariably be purulent.

Dr. Gerster reminded Dr. Oberndorfer that, whenever a general infection of the system took place from a pus-secreting focus situated anywhere in the body, one of the first symptoms was the cessation of the secretion of pus at the initial lesion. The usual method of making injections into the urethra, as practiced by the patients themselves—*i. e.*, by pressing the walls of the meatus tightly against the nozzle of the syringe—was apt to cause infection of the system by forcing gonorrhœal material into open lymph-channels in places where the mucous surface was denuded of its epithelial lining. He preferred to make the applications to the urethra himself wherever this was practicable. The fluid which he preferred was a solution of corrosive sublimate of 1 part to 5,000 or more, with which he irrigated the urethra by means of a fountain-syringe and a soft catheter.

Dr. Rudisch inquired whether the treatment of the urethral mucous membrane had any influence upon the progress of gonorrhœal iritis, if such a complication existed.

Dr. Knapp answered that in such cases he never interfered with the urethra at all, and that the discharge from the urethra always subsided without any local treatment. He thought that the good effect of antiseptics could be accounted for by their astringent property, in consequence of which they diminished the amount of transudation, and thus deprived the micro-organisms of the soil on which they fed.

Gonorrhœal Ophthalmia.—Dr. Knapp also mentioned that he had lately met with an unusual number of cases of this affection. In regard to treatment, he did not use nitrate of silver in any form in the beginning, but restricted himself to measures of cleanliness and the application of cold.

Meeting of October 26, 1883.

Dr. A. Jacobi in the Chair.

Sarcoma of the Kidney.—Dr. Aug. Seibert exhibited both kidneys of a girl ten months old, the right one of which was the seat of a medullary carcinoma. He intended to publish the case in detail at some future date.

Dr. Alfred Meyer remarked that sarcoma of the kidney occurred more frequently than carcinoma in children.

Dr. Seibert replied that in the foregoing case he and Dr. A. Seessel had become convinced, by means of microscopic examination, that the new growth was a carcinoma.

Dr. I. Adler contradicted the statement of Dr. Meyer with reference to the frequency of occurrence of both classes of new growths in the kidneys of children.

The Chairman remarked that more attention had been given to tumors of the kidney within the past fifteen years. The greater number of congenital as well as malignant new growths which developed in infants and in children of one or two years of age were found in the kidneys, and the majority of these tumors were sarcomata. Hæmorrhage hardly ever occurred with this kind of tumor. He had observed six cases of sarcoma of the kidney up to date, but had never seen one case of carcinoma. Should carcinoma occur at all in children, its favorite seat would be the kidney, but the greater number of new growths of this organ were assuredly sarcomatous.

Dr. Adler was of the opinion that most of the so-called primary sarcomata of the kidney did not originate in the kidney substance proper, but began either in the supra-renal capsule or in the pelvis of the kidney.

Sarcoma of the Left Side of the Face.—Dr. Adler presented a patient, forty-six years of age, upon whom he had operated for the removal of a sarcoma of the left side of the face five weeks previous. The tumor became noticeable about one year ago, although the patient had experienced some difficulty in mastication and swallowing for a considerable time previous, evidently caused by the new growth. At the time of the operation the region of the left parotid gland was the seat of a tumor which was of the size of an apple. Above the zygoma there was a smaller projection. The patient could not open his mouth. Under the influence of chloroform a digital examination of the fauces was rendered possible. The left tonsil and the uvula were pushed to the inner side, but were not united with the tumor.

While extirpating the tumor it became apparent that the new growth originated from the left lower maxilla, which bone, together with the muscles attached to it, with the exception of the internal pterygoid, was removed. The parotid gland was atrophied, but not involved in the tumor, and was, therefore, not removed. The number of vessels ligated was quite small; among them was the internal maxillary artery. A portion of the pterygoid process was removed. The wound was dressed with iodoform, and healed without any signs of reaction. A microscopic examination showed the new growth to be a giant-celled round-celled sarcoma. At the time of this report the patient was able to masticate.

Ossifying Giant-celled Sarcoma of the Foot.—Dr. Adler showed the foot of a girl, seventeen years of age, which he had amputated four months previous in the German Hospital. The family history of the patient was phthisical.

The patient entered the hospital in January with a swelling of one ankle joint, which was considered a fungous inflammation, and it was treated with ignipuncture. As the swelling of the joint increased, Dr. Adler determined to perform a radical operation. He made a longitudinal incision at first, as recommended by Kocher, in order to explore for an intended exsection. A peculiar substance oozed forth, which at first sight seemed to be fungous, and he determined to perform Syme's amputation at once. A microscopic examination demonstrated that this mass was an ossifying giant-celled sarcoma, which projected from the anterior surface of the astragalus. The scaphoid bone was not involved. The position of the new growth corresponded with one of the previous ignipunctures. No trace of a fungous process was found on the joint surfaces nor anywhere on the sheaths of the tendons.

Dr. Adler was of the opinion that the new growth was present at the time when the ignipuncture was performed, and that this operation caused a rapid proliferation of the same.

Dr. A. G. Gerster remembered a case which he observed about one year ago, in which a sarcoma developed itself in the bony cicatrix of a previous fracture of the external condyle of the humerus.

Adenoid Vegetations.—Dr. Aug. Caillé exhibited several adenoid vegetations which he had removed by means of Jarvis's snare from the naso-pharyngeal cavity of several patients.

Dr. Gerster said that Jarvis's instrument had broken when he had attempted to remove any dense swellings.

Dr. Adler said that he used the snare constructed by Zaufal, of Prague, with the best success.

Extirpation of the Uterus and Ovaries.—Dr. Paul F. Mundé reported a case in which he had successfully extirpated the uterus with the ovaries, at Mount Sinai Hospital. The operation was performed on account of a carcinoma of the cervix, the uterus being quite movable. The patient was placed in Sims's position and the operation performed through the vagina.

Dr. Gerster stated that Dr. Bopp had successfully removed a uterus through the vagina. He had assisted at a similar operation, recently performed in Brooklyn, on account of a total prolapse of the uterus and vagina. This latter case progressed favorably.

The Chairman remarked that the first operation for extirpation of the uterus ever performed was that done by Dr. Emil Noeggerath in Hoboken about six years ago. The case terminated fatally.

Tuberculosis of the Lung with Pneumothorax.—Dr. Alfred Meyer exhibited the lung of a phthisical patient which, becoming perforated a short time before death, caused pneumothorax.

Dr. Meyer also showed the uterus and other organs of a woman who had died of puerperal septicæmia.

Parenchymatous Inflammation and Fatty Degeneration of the Kidneys.—Dr. H. J. Boldt reported the case of a woman, twenty-nine years of age, who had been suffering with frontal headache for several years. The headache was most intense in the morning, and, as a rule, subsided in the afternoon. A short time before death the woman was seized with periodical rigors, which were not influenced by quinine. The urine at no time contained albumin. The patient was seized with convulsions which passed into coma, and in this condition she died. The autopsy did not corroborate the probable diagnosis of abscess of the brain, there being only a hyperæmia and œdema of the brain-substance.

Dr. Satterthwaite had examined the kidneys and found them in the first stage of a parenchymatous inflammation or fatty degeneration.

Meeting of November 30, 1883.

Dr. A. G. Caillé in the Chair.

Empyema.—Dr. H. J. Boldt read the full clinical history, and exhibited the lungs, of a man, twenty-two years of age, who had apparently at first suffered from typhoid fever, and afterward a pneumonia, to which he succumbed. The autopsy revealed an empyema. During life bronchial breathing could be heard distinctly over the empyema.

Dr. A. Jacobi, who saw the case in consultation, stated that he had heard the bronchial breathing, and thought that it was caused by short adhesions between the costal and the visceral laminæ of the pleura. It was always necessary, he thought, to make an exploratory puncture in doubtful cases.

Urine containing Casts but no Albumin.—Dr. Boldt also spoke of certain cases of Bright's disease in which the urine contained casts but no albumin.

Dr. Charles Heitzman remarked that this peculiarity occurred in chronic Bright's disease, and Dr. Gustav Langmann stated that it also occurred in acute cases.

Primary Sarcoma of the Kidney.—Dr. Jacobi exhibited a primary sarcoma of the kidney of a boy, two years of age, who had been admitted into Bellevue Hospital on August 8, 1883, on account of distended abdomen and occasional vomiting. On admission, the temperature was 101° F., and a swelling was found on the right side of the abdomen. On percussion, tympanitic resonance was found in the space extending between the liver and the swelling. The patient was put on a generous diet, and alcohol and arsenic were administered.

September 20th.—The patient had improved, having good appetite, but the swelling had increased in size. A diagnosis of sarcoma of the kidney was made. The urine never contained albumin or blood.

October 12th.—The swelling had become larger; there was marked dyspnœa; on the right posterior surface of the thorax dullness was present, which corresponded to a watery serosanguineous exudation, which was removed by aspiration.

The dullness over the tumor now coalesced with that of the liver, and there was apparent fluctuation at a certain point. This being punctured, some dark, bloody fluid was evacuated. The tumor continued to grow rapidly, and finally the child died, emaciated and exhausted. The autopsy revealed a large tumor of the right kidney, which was inclosed in a dense fibrous capsule, and to which the ascending colon and liver were adherent. On section, the anterior portion of the tumor revealed a cyst which contained about two hundred and fifty grammes of fluid. In the middle of the swelling there was hæmorrhagic exudation. The ureter was not degenerated, and extended up to the middle of the tumor, where it joined a normal remnant of the pelvis. The tumor itself was a soft, round-celled sarcoma.

Dr. Jacobi then spoke about the differential diagnosis of carcinoma and sarcoma of the kidney, and said that with a large tumor and a history of comparatively fair health for a long period of time the diagnosis of sarcoma was quite probable. The course or clinical history of sarcoma was also of longer duration than of carcinoma.

Osteo-sarcoma of the Right Jugular Bone.—Dr. F. C. Heppenheimer exhibited an osteo-sarcoma of the right jugular bone which was not noticed until eleven months before death. A resection was performed in Bellevue Hospital, but a new tumor very soon appeared. Finally the tumor involved the right side of the frontal bone, the entire inner surface of the orbit, and perforated the right side of the ethmoid. From the orbit the tumor extended to the right angle of the jaw, thence under the chin to the middle portion of the digastric muscle, where a round mass of the size of a small egg projected from the main portion of the tumor. From here the tumor extended backward to the anterior surface of the sterno-cleido-mastoid muscle, and upward along this muscle to the level of the lobule of the pinna. The tumor involved the entire region in front of the ear, and, passing up obliquely, was bounded by the superciliary ridge. The right eye was pushed forward and covered by the lids. The patient, who was sixty-four years of age, died of exhaustion.

Choroiditis Metastatica.—Dr. Heppenheimer showed the eyes of a patient, thirty-three years of age, who had suffered from a metastatic choroiditis. The patient died of a diphtheritic endometritis.

Carcinoma of the Stomach.—Dr. Heppenheimer also exhibited a connective-tissue scirrhus of the pyloric end of the

stomach which would have been a favorable case for exsection. The patient died of hæmorrhage from the stomach.

A Floating Body in a Hydrocele.—Dr. Heppenheimer also showed a floating body found in a hydrocele.

Carcinoma of the Œsophagus.—Dr. Alfred Meyer exhibited the œsophagus of a woman, fifty-two years of age, which was the seat of a carcinoma. In the previous July the patient experienced difficulty in swallowing and pain in the epigastric region. She vomited frequently and lost flesh and strength, finally becoming so emaciated as to weigh ninety-two pounds only. October 2d an incision was made, and an obstruction was ascertained to be situated about twelve inches from the incisors. An œsophageal bougie No. 5 was passed, which caused an amelioration of the symptom and a marked increase in weight. October 21st the patient began to vomit very frequently and emaciated very much. This vomiting was followed by coughing, the patient vomiting the contents of the stomach mixed with pus. A short time before death she weighed fifty-two pounds only. The autopsy showed a dilatation of that part of the œsophagus situated above the stricture which measured 6·5 cm. in diameter, while the diameter of the œsophagus below the stricture was 3·5 cm.

An ulcerative process, beginning at the new growth, perforated the right bronchus, thus establishing a communication between this bronchus and the œsophagus.

In the right lung a suppurative bronchitis was found. In the right axillary region a swollen gland was seen. Microscopic examination showed an epithelioma. According to von Ziemssen, this class of carcinoma of the œsophagus rarely occurred in women.

Repeated Attacks of Scarlatina in a Child.—Dr. Gustav Langmann reported a case of a boy, fourteen years of age, who had had twenty-four attacks of scarlatina. About twelve years and a half ago the patient had his first attack of scarlatina complicated with diphtheria. This occurred in the year 1871, and since that time he had had a regular attack of scarlatina every spring and fall. The rash, angina, rise of temperature, and especially the characteristic desquamation of the palmar surface of the hands, left no doubt as to the correctness of the diagnosis. The urine never contained albumin, and the temperature was seldom higher than 102° F. Dr. Langmann also stated that it was not rare for a patient to have scarlatina more than once.

Dr. William Balser had observed a case in which the patient had six attacks of scarlet fever.

Dr. Herman G. Klotz said it was important to remember that *erythema exudativum* occurred most frequently in the spring and autumn, and also called attention to the fact that, after an exanthema brought on by quinine, a desquamation of the palmar surface of the hands occurred.

A. Seibert, M. D., *Secretary pro tem.*

Meeting of December 28, 1883.

Dr. Ernst Schottky in the Chair.

Calcareous Concretions in the Sputum.—Dr. Aug. Seibert exhibited three calcareous concretions which, at various times, had been coughed up by a patient who had marked dullness at the apex of the left lung.

The patient stated that he had experienced a pain at a certain point of the thorax, which began a certain time before he had coughed up these deposits. This pain ceased as soon as the deposits were coughed up.

Interstitial Pregnancy and Rupture of the Uterus.—Dr. H. J. Boldt exhibited the uterus and appendices of a woman, twenty-one years of age, with the following history: Five days before death, while dressing to go out for a walk, she was suddenly seized with intense pain in the right inguinal region which compelled her to go to bed. She stated that she had danced on the previous day. When Dr. Boldt first called he found the patient very pale, semi-comatose, and complaining of very severe pain in the right inguinal region. The uterus was anteflexed. Twenty-four hours later peritonitis set in. On the fifth day she vomited frequently, the temperature rising to 103° F., and on the following night she died.

At the autopsy about twenty ounces of coagulated blood were found in the right pelvic cavity. This blood apparently took its origin from the posterior surface of the uterus, where a laceration was visible, and at this point a swelling was also found.

Dr. Boldt thought that the ovaries were in a state of cystic degeneration.

Dr. J. Kucher was of the opinion that Dr. Boldt's case was one of interstitial pregnancy, and that the swelling found on the uterus was probably placenta.

Dr. H. Garrigues was of the same opinion as Dr. Kucher, and did not think that the ovaries were degenerated, but that the right ovary, which apparently was degenerated, simply contained a corpus luteum.

Cheesy Degeneration of the Lungs.—Dr. Boldt also exhibited the lungs of a child which he had presented to the meeting on February 23, 1883. Craniotabes was diagnosticated at that time. The lungs contained cheesy deposits. The bronchial glands were enlarged.

Tuberculous Meningitis of the Convexity of the Cerebrum.—Dr. A. Jacobi exhibited the convexity of the hemispheres of the cerebrum of a man fifty-one years of age, whom he was called to see in consultation with Dr. Herzog on December 19, 1882. Dr. Herzog was called because the patient suffered from a severe headache and complained of irritability. His family history was negative. The pulse during the course of the disease only sank as low as 64 beats on one occasion. December 14th the patient was seized with spontaneous vomiting. On December 19th, when Dr. Jacobi first saw the patient, he found the left pupil considerably dilated. The naso-labial fold had disappeared. The patient presented a typical case of *taches méningitiques*. The heart and kidney were normal. A diagnosis of tuberculous meningitis of the convexity of the brain was made. The localization of the diagnosis was made on account of the small degree of irritability of the pneumogastric, which was demonstrated by the fact that the frequency of the pulse was very little changed. The post-mortem confirmed the diagnosis.

Sublimate Dressing.—Dr. H. J. Garrigues showed the sublimate dressings which he used with good results in the Maternity Hospital.

Dr. J. Kucher considered the dressing superfluous, because the infection occurred during parturition. This fact was proved by the well-known immunity from puerperal fever in cases where labor set in unexpectedly on the street.

Dr. J. Rudisch pointed to the fact that previous to the introduction of antisepsis a favorable result was frequently obtained in the intervals of endemics of puerperal fever, and that a similar interval possibly occurred in the case of Dr. Garrigues when he employed the antiseptic dressings.

Dr. A. Jacobi said that the type of puerperal fever prevailing in the Maternity Hospital when Dr. Garrigues employed the dressing was diphtheritic, and that the favorable results observed by Dr. Garrigues occurred at a time when diphtheria was prevalent in the surroundings of the hospital in the same proportion as before the introduction of the sublimate dressing, so that the favorable statistics now obtained must bear some relation to the employment of this dressing.

Dr. A. G. Gerster remarked that he used a similar dressing in lithotomy, and that this dressing prevented putrefaction of the urine. A. G. Gerster, M. D., *Secretary*.

Miscellany.

The International Medical Congress.—"Gaillard's Medical Journal" publishes the following letter from a correspondent who signs himself "Old Code":

"Although not wishing to trespass upon space which might be more profitably devoted by you to scientific material, I desire, nevertheless, to present for your consideration, in connection with the matter of the Ninth International Medical Congress, several principles which thus far in the discussion of that unfortunate subject seem to have escaped general attention, and which, if rightly understood and applied, would, I believe, set at rest much existing controversy. They are the principles upon which the International Congress as an institution was first conceived, and upon which, up to the present time, it has maintained a most successful career.

"I. The International Congress is essentially an independent, self-perpetuating body. It is independent because its objects are *purely scientific*, and its organization possible only upon that basis. It is self-perpetuating because capable of appointing its own officers and of electing its own places of meeting. Its hitherto uninterruptedly successful career places the fact of its perpetuity beyond a doubt.

"II. The Congress is, as its name implies, distinctly *international*. As an institution, therefore, it can not by any possibility be considered the property of an individual, country, or party. Should such proprietorship be admitted at all, it could only be in the case of those who originated the enterprise and who have conducted it through its eight successful meetings. Since this is so, it would seem not only wise and courteous, but, in fact, absolutely necessary, that local issues be placed as far as possible out of sight.

"III. The profession of any given country in which a regular meeting may be convened have certain privileges (as of entertainment, general arrangement, etc.) committed to them, as it were, *in trust*. The entertaining body has, of course, its own share in the governance of the Congress as a whole, just as any other country represented, but it can not possibly be conceded to have full controlling power. While accepting and exercising in full the privileges accorded to us as the organizers and entertainers of the Ninth Congress, we are still compelled to recognize our *trusteeship*, and we are under obligations, when we have finished with the institution, to leave it in the same sound condition in which it was received.

"IV. It is, clearly, the *whole body* of the International Congress which should dictate its policy. The expressed wish of the Congress must be accepted, therefore, as the controlling line of action. When, at Copenhagen, it was proposed that the next Congress be held in Washington, before the question was put for decision to the Eighth International Congress then assembled at its final general meeting, it was distinctly understood by those in charge that political issues in general, and the so-called 'code issue' in particular, *were not to be admitted*. It was as plainly understood that the representation was to be of '*the medical profession of America*.' Upon the strength of these propositions the vote was carried unanimously.

"Thus, in the present condition of affairs, we appear before the world not only divided against ourselves, but, what is far worse, as having set aside the distinct compact made with the International Congress itself, having acted in direct defiance of the principles by which it has heretofore been controlled, and having placed ourselves in clear opposition to its expressed wishes.

"Regarded from the International, and, therefore, from the true and broad standpoint, questions relating to local politics, local organizations, or local sentiments have in this matter no place. They are, most absolutely, out of order.

"When the above principles are thoroughly understood by the profession of this country at large, and when it is also understood that it is only upon them—that is, upon the principles of its own adoption—that the International Congress will allow its policy to be conducted, we may hope that the present dilemma may be removed and further disaster averted. I trust that this most desirable issue may await us in the very near future."

The "Medical Times and Gazette," of London, says:

"The 'Lancet' has not taken up a wise line in reference to the Washington Congress. It has either been misinformed as to the facts and the importance of the unfortunate dispute now going on in America, or else it has willfully shut its eyes to them. It is absurd, for instance, of the 'Lancet' to attempt to minimize the differences which have caused the withdrawal from the Congress of almost every man of mark in America. The fact that nearly every medical journal of any repute in the United States has vigorously condemned the action of the American Medical Association, and given its warm support to the men who are contending for the freedom of the profession against the selfish designs of a clique, should in itself have induced the 'Lancet' to give a little more attention to the question before taking the wrong side with such a light and careless heart. The sole fact that seems to weigh with the 'Lancet' is that Dr. Flint has been appointed President of the Congress, or rather that his original appointment has been confirmed by the new committee. Dr. Flint's is no doubt a powerful name to shelter one's self behind. He is incontestably one of the most eminent representatives of the profession in the United States, and it has been a source of profound sorrow to those who have felt constrained to withdraw from the Congress that in doing so they have had to part company with him. But we can not blind ourselves to the fact that Dr. Flint, eminent and honored as he is, has in the present instance allowed himself to be made the instrument of a minority. The part which Dr. Flint would take in this lamentable strife has been foreseen and discounted. The men of Boston, Philadelphia, and Baltimore who withdrew from the Congress knew that he would not follow them. The fact is that Dr. Flint is bound up with the American Medical Association, and an honorable feeling of loyalty no doubt constrains him to accept its decisions, however much he may deplore them in his secret heart.

"If the British Medical Association—a body five times more representative of the English profession than the American Medical Association is of the profession in the United States—had played the same part in reference to the London Congress that the American Association is attempting to play in connection with the Washington Congress, the 'Lancet' would not have been able to find language strong enough to use in condemnation of such action, and we are simply at a loss to understand the reasons which have actuated its present policy. Surely the 'Lancet' can not have realized the fact that the American Medical Association—*i. e.*, a body representing only ten per cent. of the profession in the United States—has decided that no American practitioner shall be admitted to the Congress who is not either a member of the association or a delegate appointed by a State or county medical society. In other words, if the American Medical Association has its way, between thirty and forty thousand American practitioners will be kept as much outside the Congress as if they were not medical men at all. Is the 'Lancet' prepared to give its support to a narrow and illiberal innovation of that sort? Would our contemporary be surprised to learn that this question of principle will henceforward form the main ground of conflict? It may be answered that any American practitioner can purchase the right to become a member of the Congress by joining the American Medical Association. True, but will the foreign visitors let the Congress be thus turned into an instrument for forcing men to join the association who would not join it of their own free will? It is evident that on this question all the leading men who have withdrawn from the Congress will be on the same side with the thousands of practitioners who are at present outside the American Medical Association. And on the other side whom have we? Dr. Flint, the wire-pullers of the association, and the 'Lancet.'

"We are very sorry that our contemporary has committed itself to that side, which every one who knows the facts and judges them with sobriety must admit to be the wrong one. Its American readers will

scarcely welcome such ill-timed and ill-instructed advocacy. The only hope for the Congress lies not in a postponement of disputes till after it is over, but in an unconditional surrender by the American Medical Association of the position which it has so unwisely taken up, aud in the rehabilitation of the original committee. On these points we believe that the leading men who have retired from the Congress are unanimously determined, and will admit of no compromise. If they still stand aloof, there will be no Congress, in spite of the 'Laucet's' confident prophecies. Our contemporary seems hardly to realize the extent and importance of the withdrawals. To take one section alone, that of ophthalmology, not more than four or five men of any reputation are left on it. Dr. Agnew, Dr. Knapp, and Dr. Jones, of Chicago, have been removed from their offices by the new committee of the American Medical Association, while Drs. Thomson, E. Williams, Burnett, Derby, Norris, Seely, Theobald, Wadsworth, and H. W. Williams have all declined to hold office in counection with it. A similar state of things prevails in almost every other section, so that, unless the practitioners who have withdrawn can be induced to return, the European guests who go to Washington in 1887 in search of scientific discussiou will have to provide it for themselves. Under such circumstances, we doubt if many will care to encounter the discomforts of the Atlantic passage."

The "Journal of the American Medical Association" publishes the following letter from Dr. John H. Packard, of Philadelphia:

"In an editorial in your issue of August 15th it was stated, on what authority I do not know, that I had withdrawn my declination of the secretaryship of the International Medical Congress of 1887, and consented to assume that office. The truth is that up to the present moment no official notice of such nomination has been sent me, nor has any publication of it been made to my knowledge, except in the 'Medical News' for July 4th. I do not, however, wish to make any point of this, but beg that you will afford me space for a plain statement, as brief as I can make it, of the facts in regard to this matter.

"On or about the 1st of June the chairman of what is now known as the enlarged committee told me that Dr. Billings would probably decline the office of Secretary-General, and asked me if, in that case, I would accept the nomination. I told him I would not seek any office, but that if it should appear to be for the promotion of harmony and of the success of the Congress, and the nomination were offered me, I would seriously consider whether I could undertake the work.

"After the enlarged committee had met in Chicago, a meeting of physicians was called here to receive a report of what had been done. I was at this meeting for a few minutes only, and did not hear the report, or know that it concerned me. Subsequently I was told that my nomination as Secretary-General had been announced, and that the impression had been conveyed that I had been a party to ousting Dr. Billings in my favor—in other words, that I had intrigued to obtain a place not vacant. I have since been told by the secretary of the committee that my nomination came from an outside source, and without any prompting on the part of those with whom I might have been supposed to be in league. How any one who knew me should think me capable of action so completely at variance with my whole life I could not and can not understand. Yet I found myself under this imputation, and felt compelled to subscribe my name to the protest of June 29th, lest my not doing so should give color to the idea that I had so schemed.

"There was another reason, not of a personal character, for my joining in the protest. The enlarged committee had adopted a rule which limited the conditions of membership, so far as Americans were concerned, while it left to foreigners free and untrammeled admission. Of this I could not approve. I at once wrote to the secretary of the committee and declined the nomination as Secretary-General, in advance of official notification, on the grounds that I was informed that Dr. Billings had not intended to resign, but had done so only because of the action of the enlarged committee; that the committee originally appointed had resigned; and that it was likely that the change of management would cause forfeiture of the foreign support of the Congress, as well as of much of that expected from the profession in this country. This letter I have not withdrawn.

"When I understood that there was hope of a compromise being effected in regard to the matters in dispute, and the propositions looking thereto were shown me, it seemed to me that they were faulty in that they dealt with the American membership only; and I ventured to submit one simply defining the conditions upon which any one, American or foreign, might come in. In handing this to Dr. Shoemaker I gave him also a note of explanation, in which I said that if anything better was offered I would gladly accept it. So far as I know, this was the only expression of mine which could be construed into a withdrawal from my former position.

"My own conviction is that it is contrary to all precedent for the American Medical Association to assume any control of the management of the Congress, which is a body by itself, and the members of which will be in no sense the guests of the association, or subject to it. Were I Secretary-General of the Congress I should not consider myself the appointee of the American Medical Association, nor responsible to it in any degree.

"And while it is eminently proper that the profession all over the country should be welcomed to membership in the Congress, and to a full share in its proceedings, the association does not seem to me to be, in its present form, a sufficiently representative body to undertake to insure this, even if it could properly claim the right to do so.

"I trust that you will bear with me in what is perhaps the wearisome length of this statement of facts aud opinions; but it has seemed to me to be due not only to myself, but to those who have been kind enough to consider me worthy of nomination to office in the Congress.

"No one can regret more than myself the prospect of wreck of a scheme in which the credit of the American profession is so deeply involved; and to avert it I would gladly do all in my power, but can not sacrifice my personal honor or stifle my convictions."

The "Medical Record" says:

"The 'Journal of the American Medical Association,' which has so steadily maintained a character for dignity and dullness, has recently lost its first attribute at least, without perhaps undergoing much change as regards the second. Its endeavors to prop up the present managers of the International Congress have led it into a curious position. It is no longer the organ of the profession, or even of the association, but is rather a strident defender of the clique who are bent on having their own way. Despite the almost universal condemnation of the policy developed at New Orleaus and Chicago, the 'Journal' continues to defend it. In doing so, it has uot had the courage of other journals, which it accuses of being 'organs,' but has systematically repressed all adverse critical comments even from disinterested European brethren. It has sneered at the eminent gentlemen who have withdrawn from the association, and has characterized them as thoughtless and foolish malcontents. Although resignations have now been going on steadily for over two months, it still chooses to regard the action as 'hasty.'

"With all this, however, we are each week informed that, if the withdrawing members will hurry up and return to the fold, it may not yet be too late for them to be forgiven! The 'Journal' is in much the position of a man on a raft, who threatens the passengers of a stanch ship with all the dangers of the sea if they do not soon come down and help him navigate.

"Last of all, the 'Journal,' to help itself along, has been guilty of misstatements, which, however, we can easily believe were accidental or typographical. We quoted last week from it the announcement that Dr. John H. Packard had withdrawn his resignation. We have the authority of the 'Medical News' that this is not true.

"Our Chicago contemporary, in discussing the question, has in every instance evaded the real issue, viz., that there should be no politics in a scientific convention. The introduction of this issue it can not excuse, and wisely has not attempted it.

"From its last announcement, we infer that no serious attempt at compromise is to be made. The present managers will, it is true, change the rules so that any regular physician can be a member of the Congress. But it is simply an insult to intelligence and self-respect to assume, as is done, that this is any concession. Gentlemen of new-code affiliations can contribute in money and work, but can not share the honors!

"There is a demand from the whole American profession, from that of England, Germany, and the other countries of Europe, that the code

issue he entirely left out. Will not the committee, which is to meet in this city on September 3d, respond to this demand? It would not be very difficult, and the success of the Congress would then be assured."

Vaccination after the Beginning of Small-pox.—As we have taken the ground that this practice is useless, we think it only fair to give heed to respectable testimony to the contrary. We therefore quote the following letter, addressed to the "Lancet" hy Dr. Francis J. Allan, of Edinburgh:

"On the evening of April 12th last I was called to see C. R——, a domestic servant, aged twenty years, with the following history: She had come to this situation on April 1st, feeling well, but at the end of a week she began to complain of lassitude and headache, and on the 10th and 11th these were accompanied by sickness and pain in the throat, back, and limbs. On the 12th a few papules appeared on the forehead, neck, and body, and on the legs were large red patches. When seen in the evening the girl said she was 'all right, except for the spots.' From the symptoms and the character of the papules a mild form of small-pox was diagnosed. The girl was removed next day to the small-pox hospital, and the other inmates of the house were revaccinated. C. R——'s fellow-servant, C. L——, eighteen years of age, who had occupied the same bed up to the 11th, complained at the time she was revaccinated of loss of appetite, and her arms were noticed to be rough, which she said was unusual. Next day (the 14th) she had severe pain in the back, the tongue was thickly furred and the fauces inflamed, with four small painful raised spots visible; temperature in right axilla 103° F. The patient had been excited and delirious during the night. On the 15th several papules were seen on the face, and the pain was not so severe. Meanwhile the left arm was becoming red and swollen at the seat of vaccination, which was evidently 'taking.' On the 16th the hard papules on the face were disappearing, and the skin of the legs and arms was desquamating slightly. The pain in the back continued until the 19th, by which time large vesicles had formed on the vaccinated arm, the four large pocks looking more like the result of a primary than a second vaccination. In a couple of days the pocks were at their height, and, with the exception of some swelling of the axillary glands and general weakness, the patient felt comparatively well. The skin very soon became clear and smooth, and she was able to resume her usual employment in a fortnight from the first appearance of the small-pox symptoms. On the others (four persons) in the house the vaccine took full effect. No other cases of small-pox have occurred in the house or vicinity since.

"No cases of small-pox had been known in the neighborhood for several months; and, as the incubation stage is of about twelve days' duration, it was presumed that C. R—— had been exposed to the infection previously to her taking the situation on April 1st. On the 12th the papules appeared, so that, allowing two days for the stage of invasion and twelve for that of incubation, it is probable she was exposed to the infection about March 29th. C. L—— slept in the same bed with C. R—— until April 11th, and, making the same allowances, possibly the poison entered her system the first night C. R—— slept with her. Even if the stages were shorter, it still shows that the infection may be communicated at a very early stage of the disease. A more important point is the action of vaccine as an antidote to small-pox. It has been asked, Is it worth while to vaccinate a patient who is beginning to show symptoms of small-pox? This case (C. L——'s) answers the question to the effect that small-pox may be checked, if vaccination be done with good lymph, even as late as the end of the incubation stage or the beginning of that of invasion. In this case, from the severity of the prodromal symptoms, the attack of small-pox would have been a correspondingly severe one; and this is borne out by the large typical vaccine vesicles produced, showing the great susceptibility of C. L—— to the small-pox poison. Evidently, it was the more rapid development of the vaccine which saved the patient from a virulent attack of the more slowly growing small-pox."

A Reminiscence of the Royal Society.—T. Wharton Jones, F. R. C. S., F. R. S., treats the readers of the "Lancet" to a recital of the part which he played, some fifty years ago, in the investigation of the ovarian ovum. He recounts having combated "the erroneous views of the late Dr. Martin Barry . . . . which were promulgated with the support and encouragement of the 'Royal Society of London for *promoting* Natural Knowledge' and of all the 'scientific world of London'—that is, a clique of the professing physiologists in London, who had got virtual possession of the Royal Society, and arrogantly pretended to decide what ought and what ought not to be considered facts in nature without themselves knowing anything whatever of the subject, for lack of original investigations of their own." Our author writes under the following noteworthy caption: "On the Ova of Man and the Mammifera before and after Fecundation. Historical Notice of the Discovery of the Germinal Vesicle of the Mammiferous Ovarian Ovum, and of the Recognition of a Superadded Investment around the Ovum of the Rabbit as it Presents itself in the Fallopian Tube after Impregnation: a Single-handed Struggle against the whole so-called 'Scientific World' of London Fifty Years Ago. *Dedicated to the Scientific World of the Present Day.*"

The "Journal of the American Medical Association."—In the course of an editorial article entitled "The International Medical Congress and the American Medical Association," the "North Carolina Medical Journal" says: "We trust that, whether we have an International Congress in the United States or not, the dilemma now puzzling the wisest men in the American Medical Association may be overcome, and that such safeguards may be devised as will give the smallest scope for medical politics in the future. It is almost marvelous that such a threatening condition of things was never before reached when one analyzes a few of the huge meetings of the association. It is evident now that, in the future, the opportunities for medical politics must be reduced to a minimum, and every effort made to make the production of scientific work the chief object of the association and a test for preferment. We do not sympathize at all with the suggestion that a new national society should be formed. Secession is a costly business—it arrays good friends against each other, consumes valuable substance, and is so liable to end at last in striking colors you have pride in, and in grounding your arms to an enemy having the only advantage over you in being more numerous and better fed. For these and other reasons we prefer to encourage every means which will make the American Medical Association what the British Medical Association is, and we believe that the surest means to this end is to build up the journal of the association; for no one can doubt, although of late some of the editorials on the Congress have been acrimonious, that the editor has all the qualities of an earnest heart."

Homœopaths and Homœopaths.—We find the following in a very interesting presidential address, entitled "The Latest Systems in Medicine," lately delivered before the Ohio State Medical Society, by Dr. J. C. Reeve, of Dayton:

"The diversity of homœopathic doctrines shows that the term 'homœopath' does not define a man's position with any accuracy at all. It covers very diverse, even opposite opinions. This fact has an important bearing upon the medical politics of the present. You know that our sister society of New York has been divided upon the question of consulting with homœopaths. It would be well for us, therefore, so long as this question remains a possible one for this and other societies to consider, to understand as clearly as possible what the term 'homœopath' implies.

"It includes, at least, three distinct and well-defined classes: A few homœopaths are Hahnemannians. At the meeting of the New York Homœopathic Society in 1883, three acknowledged themselves to be such out of sixty present. According to the 'British Medical Journal,' the real homœopathists of Great Britain can be counted on the fingers of a single hand. With this portion of the sect it is impossible to consult. You can not reason with a man who maintains that a part is greater than the whole. These are intellectual cranks.

"A considerable larger portion of the sect is made up of those who have been educated in all the branches of medical science, who practice in good faith according to the law of similars, but who are bound by no rigid rules as to dose. This class is more numerous in Eastern cities than here. It is large enough to have an organ. This journal carries at its head this extract from our code of ethics: 'A regular medical education furnishes the only presumptive evidence of professional abilities and acquirements, and ought to be the only acknowledged right of

an individual to the exercise and honors of his profession'; and this: 'Our practice is *not* based on an exclusive dogma, to the rejection of the accumulated experience of the profession, and of the aids actually furnished by anatomy, physiology, pathology, and organic chemistry.'

"These men comprise the best of the sect. They support medical legislation to establish boards of health and insure to the public educated physicians. They are on their way back to the ranks of the profession; they are dropping their distinctive appellation, and certainly no obstacles ought to be placed in the way of their return. It is folly, and worse, to call them charlatans and quacks. They are men who exaggerate the value of the law of similars, and the efficacy of the small dose. There is room for honest difference of opinion as to the range of the law, and it will not do for men who use 'Ringer' as a text-book to be too particular about small doses. These men are but little farther from the general line of practice than many of our number who ride 'hobbies,' who appear so frequently in the journals with new and wonderful modes of treatment of diphtheria, scarlet fever, or of some other epidemic they have passed through. We smile at the enthusiasm of these men, we recognize their error to be the same as that of the system-makers, generalizing from a few facts, we glean from their bushel of chaff the few grains of truth there may be; we do not cut them off from professional fellowship. We ought to treat as professional brethren all men who have been educated in medicine, who are honorable in conduct, who elevate the profession above any of its sects, who are honestly trying to advance our knowledge, and to cure disease and alleviate suffering, whatever may be their methods.

"The majority of homœopaths are unfortunately of quite another character. They have adopted this line of practice for whatever there may be of popularity in it, and they pursue their calling in the sole spirit of trade. Shall I be charged with slandering my neighbors? Hear what the 'Medical Times' says. It has dropped the distinctive title of 'homœopathic,' and advises others to do the same: 'We are as confident as we can be of anything that many use the term from mercenary motives, and that it is in many instances only a trade-mark!' The editor says further that the reply to this advice always is that practice would be lost in doing so: 'With this fact in view, how can we reach any other conclusion than that the title is retained for the purpose of business?' In plain English, this means that they are obtaining money by false pretenses. These are the men who have kept bright the spirit of the founder—hatred of the regular profession. They habitually indulge in the grossest misrepresentations of regular practice, and play upon every prejudice which exists, or which they can excite, in the public mind. They sneer about 'drugs.' It is a good word to use; it sounds like *dregs*, and dregs means dirt. They boast much of using 'pure medicines,' thereby conveying the slander that others are not careful about the quality of the chemicals they administer. They instill into the minds of their patrons the fear of 'strong medicines,' and, while doing so, deal out '*lachesis*' (serpent venom) and '*crotalus*' (the poison of the rattlesnake)—medicines which are too strong for our pharmacopœia. They emphasize the single-medicine doctrine while dispensing several different kinds to be given at intervals of ten or fifteen minutes. These are the men who prate of being the 'advanced thinkers' of the age, implying that no one else is trying to extend the knowledge of cure of diseases, while they bitterly oppose all efforts to enforce thorough medical education. These are the men who, to prevent the establishment of boards of health, go to the public and whine about 'class legislation!' These are the men who are homœopaths in one house, and in the next are anything that will suit. With these men we can not consult. We want a basis of common honesty, at least, to say nothing of that dignity and education which should attach to a profession which deals with the dearest interests of humanity. We must treat them as we do those of our own practice, who, with unblushing impudence, placard the walls and fill the columns of the daily papers with boasts of their superior skill and false statements of cure.

"But all members of our profession who advocate consulting with homœopaths may set their minds at rest. The homœopaths do not want us to consult with them. When we decline to meet them, there is a loud outcry about professional intolerance and bigotry and persecution. But during this great movement in the State of New York to terminate this schism and bring about common consultations, not a motion in its favor was made on their side of the house. I have looked carefully through the files of their journals, but failed to find one word of friendly advance. Of course, schisms and sectarianism do not elevate medicine, or increase respect for it, any more than they do religion. It were better if this division was closed. But, judging from the spirit of the times, it will be a long time before this sect disappears. The better portion of the homœopaths make no organized effort toward reunion; those who ply it merely as a money-getting calling will never leave it as long as principles and prejudices exist in the human mind which make it profitable."

The Canada Medical Association.—We learn from the "Canada Lancet" that the following are the papers promised up to the 19th ult. for the Chatham meeting: Dr. Osler (Philadelphia), "The Clinical and Pathological Relations of the Cæcum and Appendix"; Dr. A. Grant (Ottawa), "Aortic Aneurysm, with a specimen"; Dr. W. B. Geikie (Toronto), "Retroversion of the Gravid Uterus"; Dr. Burt (Paris), "Internal Urethrotomy"; Dr. Holmes (Chatham), "Puerperal Mania"; Dr. Kerr (Winnipeg), "Fractures in the Neighborhood of Joints"; Dr. Fenwick (Montreal), "Amputation of the Breast, with cases"; Dr. Bethune (Wingham), exhibition of specimens: 1. "Parasite from an Abscess of the Thigh"; 2. "Aneurysm of the Pulmonary Artery"; Dr. Worthington (Clinton), "Epidemic Cerebro-spinal Meningitis"; Dr. Fulton (Toronto), "Subperiosteal Amputation"; Dr. Campbell (Seaforth), "Trephining the Mastoid Bone"; Dr. Rutherford (Chatham), "Supra-pubic Urination"; Dr. Lett (Guelph), "Inebriety, a Disease the Result of Physical Causes"; Dr. A. H. Wright (Toronto), "Phlegmasia Dolens"; Dr. McKeough (Chatham), "Pilocarpine in Puerperal Eclampsia"; Dr. J. E. Graham (Toronto), "Dissecting Aneurysm of the Thoracic Aorta, with specimen"; Dr. Shepherd (Montreal), "Excision of the Tongue"; Dr. Alloway (Montreal), "Puerperal Septicæmia"; Dr. Ryerson (Toronto), "Atrophic Nasal Catarrh"; Dr. Atherton (Toronto), "Abdominal Section for Uterine Myomata"; Dr. Nattress (Toronto), "Field Hospitals in the Northwest Territory"; Dr. A. E. Hanna (Lansdowne), "Enlarged Prostate"; Dr. Gardner (Montreal), "Double Uterus, with specimen"; Dr. Oldright (Toronto), "Pernicious Anæmia"; Dr. Ames (Brigden), "Rattlesnake Bite"; Dr. Wilkins (Montreal), "Specimens illustrating the Infective Nature of Tuberculosis"; Dr. Stewart (Montreal), "The Curability of Chronic Infantile Paralysis."

Ominico.—Mr. Stanley W. Neuer, the manufacturer of this new disinfectant preparation, has received the following letter from Dr. Edward R. Mayer, of Wilkesbarre, Pa.:

"Since you have made known to the public the constituents of your ominico compounds, there is no longer any objections to my replying to your request for a brief statement of the experiments made with it by me and of their results.

"This compound, which is a scientifically prepared solution of boracic acid, chlorate of potassium, chloride of sodium, and thymol, possesses active properties as a disinfectant and as an alterative to inflamed cutaneous and mucous surfaces. I have used it with excellent effect in many of those diseased conditions of the mouth, throat, and nasal passages in which Listerine and phenol sodique have been hitherto employed by medical men, and I regard it as not only a safe and very agreeable mouth-wash, gargle, and application for spraying, but as one having great efficacy in many cases of catarrh, sore throat, cankers, and in some chronic skin affections."

Dr. J. A. Murphy, of Wilkesbarre, writes as follows:

"I carefully indorse every word Dr. Mayer says of your ominico aseptine compounds, and will simply add that, after using almost every remedy recommended by the profession for the past ten years in the treatment of chronic nasal catarrh, I have found nothing so agreeable and to afford so much relief as your compound."

Sanitation and Milk.—The production, care, and handling of milk and its preparation for the market under the observance of the most rigid sanitary and hygienic conditions is a subject to which the medical profession has, so far as we know, given but little if any attention. These conditions, so essential for the production of a pure grade of

milk, are beyond the facilities of the ordinary milk-producer, involving, as they do, regulating and watching the physical condition of the cow; the quantity and quality of her food; the cleanliness of the stable; the entire absence of everything giving rise to odors in the dairy—as milk readily absorbs and retains any smell, such as that of rancid milk, manure, tobacco, etc.—the proper and careful cooling of the fluid; and, lastly, the complete disinfection and cleaning of cans or bottles in which it is sent to the consumer.

A recent visit to the dairies of the "Echo Farm Company," situated in the towns of Litchfield, Bantam, and Washington, Conn., demonstrated to us the possibilities in this direction. There absolute cleanliness is the rule and not the exception. The milk, as it is received from the various farms, is carefully strained into cooling tanks, in which the temperature is reduced to about 55° F., in which condition it is drawn into bottles that are hermetically sealed and packed in ice for the market. Tests of the cream-producing qualities of the milk are made weekly—the average being from 15 to 17 per cent. A competent medical man makes frequent and thorough inspections of the cows, their food, and the sanitary condition of their stables, and nothing that sanitary and hygienic laws can demand for the production of an absolutely pure milk is left undone.

THERAPEUTICAL NOTES.

Napelline in the Treatment of Odontalgia.—Grognot ("Bull. gén. de thérap.") gives brief notes of a number of cases in which he has used Laborde and Duquesnel's napelline, which, being obtained from *Aconitum napellus*, is to be distinguished from the substance to which Groves gave the same name, but which he extracted from *Aconitum ferox*. The author's plan was to give a granule of half a centigramme (= about ·075 of a grain) by the mouth every fifteen minutes. Notes are given of six cases, in only one of which did no notable improvement take place. Usually the pain was stopped or greatly mitigated by the time four or five doses had been taken. One of the cases was of two years' standing.

Salicylate of Cocaine in the Treatment of Trigeminal Neuralgia.—Schneider ("Allg. med. Ctrl.-Ztg."; "Ctrlbl. f. d. ges. Therap.") relates the case of a woman in her third attack of neuralgia of the second and third branches of the trigeminus. The first attack, five years before, had been treated successfully with large doses of quinine. The second attack lasted almost six months; quinine was of no avail, but the pain gradually disappeared under the use of morphine and iron. The third attack had continued four weeks when the author injected salicylate of cocaine experimentally. The effect was extraordinary; six grains of the salicylate, injected into the cheek, caused the pain to disappear entirely, and occasioned a general feeling of well-being wholly free from any unpleasant collateral phenomena. The injection itself was painless and did not give rise to irritation. The patient was enabled to sleep at night, although before the pain had been most severe at night. Eight such injections were given in the course of six days, and after that there was no pain except at the site of the injections, which was overcome by three applications of galvanism with the anode applied to the seat of the pain and the cathode to the back of the neck.

The Dose of Codeine.—Schneider (*Ibid.*) contends that the usual doses of codeine and its salts are quite ineffectual. In about thirty cases he has used it in doses ranging from a grain and a half to three grains, with the result of producing sleep for four or five hours or for the entire night, and without any unpleasant effects, except vomiting in one instance. He regards the drug as a great boon for victims of the morphine habit while they are under treatment, acting as a substitute and a palliative. In such cases he gives a grain and a half every three hours.

Resorcin in the Abortive Treatment of Gonorrhœa.—A. J. Munnich, of Amsterdam ("Monatsh. f. prakt. Dermat."; "Ctrlbl. f. d. ges. Therap."), has been led by a suggestion of Andeer's to try the effect of injections of resorcin in the treatment of gonorrhœa. He began with a two-per-cent. solution, but, being dissatisfied with the results, soon proceeded to the use of a three-per-cent. solution. One hundred and eight cases were treated; sixty-seven successfully, and forty-one unsuccessfully. The method was as follows: The patients were told to drink as much water or milk as they could, so as to be able to wash the pus out from the urethra by urinating before each injection. The patients managed the injections themselves, taking one every two hours by day and two during the night, and they were instructed to let the liquid flow out from the urethra at once. They usually reported on the fourth or fifth day, and in most cases the discharge was very decidedly diminished where it had been profuse, or at least not increased where it had not been copious from the start. When the night injections were omitted, the improvement of the day before was usually lost, and the duration of the case was lengthened. The injections were now reduced to three or four during the day and one at night, and in general, in the cases recorded as successful, the discharge was exceedingly slight on the seventh day, and had entirely disappeared on the fourteenth. In the cases set down as unsuccessful, *i.e.*, in which the discharge became prolonged or the deep part of the urethra was affected, at least the acute symptoms were always rapidly overcome. In only one instance was it necessary to discontinue the use of the injections on account of inflammatory symptoms, and in that case the patient had retained the solution too long in the urethra. The quickest and best results were obtained when the patients presented themselves soon after the appearance of the disease. The author thinks that still better success might be achieved in many cases by means of absolute rest and perhaps irrigations with weaker solutions.

Piscidia Erythrina in the Treatment of Dysmenorrhœa.—"Nouveaux remèdes" gives the following formula:

Mint water	120	parts;
Tincture of *Piscidia erythrina*	8 to 12	"
Syrup	30	"

A tablespoonful to be taken three or four times a day.

Scopolia Luridus.—According to Waring ("Pharm. Jour."; "Nouveaux remèdes"), this solanaceous plant, which is found at Nepaul and in the Himalayas, is equal if not superior to belladonna as a mydriatic. A tincture, made with one part of the leaves to eight parts of alcohol, causes such a dilatation of the iris that in two cases it gave rise to blindness, which did not disappear until the use of the drug was discontinued. The largest amount thus far given in twenty-four hours is twenty drops. The author recalls Christison's experiments with the drug.

Iodized Phenol in the Treatment of Whooping-cough.—Rothe ("Memorabilien") announces his continued satisfaction with carbolic acid as a remedy for whooping-cough, after fifteen years' experience with it. The formula employed is as follows:

Carbolic acid, Alcohol, each		7½	grains;
Tincture of iodine		5	drops;
Peppermint water		750	grains;
Tincture of belladonna		15	"
Syrup of diacodium		150	"

A teaspoonful is to be given every two hours, the administration being continued until the paroxysms entirely disappear.

Salix Nigra as a Sexual Sedative.—Dr. F. F. Paine, of Comanche, Texas ("Med. Age"), speaking from five years' experience with this drug, states that during a practice of fifty years he has not used a remedy that has yielded more satisfactory results. He recommends it particularly as an anaphrodisiac and as a remedy for ovarian irritation, including certain cases of dysmenorrhœa. He gives teaspoonful doses of Parke, Davis, & Co.'s fluid extract of the buds three times a day. He thinks it has something of a specific action on the nerve supply of the sexual apparatus in both men and women.

Buttermilk as a Remedy for Vomiting.—Dr. J. H. Owings, of Deer Lodge, Montana ("Maryland Med. Jour."), states that he has used buttermilk for the purpose of checking vomiting for ten or twelve years past—in as many as fifty cases, he thinks—without a failure. He knows of no other remedy equally satisfactory, and regards it as especially serviceable in cases of severe vomiting after a prolonged debauch.

Inodorous Iodoform.—The "Lancet" says that, according to M. Gillette, iodoform may be rendered inodorous by adding 1 part of sulphate of quinine and 3 parts of charcoal to 100 parts of iodoform.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M. D., NEW YORK.

(*Continued from page 257.*)

ELECTRICITY IN SPASMODIC AFFECTIONS.

HYPERKINESIS is frequently encountered as one of the varied forms of external manifestation of irritative and destructive lesions of the central nervous system. For example, it is by no means uncommon to observe convulsions (of the clonic or tonic type), tremor, muscular rigidity and contracture, etc., in connection with morbid changes in the brain and spinal cord. By these symptoms we are often assisted in determining the seat of the lesion, although, as De Watteville remarks, "the pathogeny of spasm is one of the most obscure problems in neurology." On the other hand—in many instances chorea, epilepsy, hysteria, etc.—spasm may exist without any apparent structural changes in the nervous system, being excited by some source of reflex irritation—such as phimosis, visual defect, uterine displacement, insufficiency of the ocular muscles, etc. In tetanus the exciting cause is generally found in one or more of the peripheral nerves. Sclerosis of the motor fibers of the lateral columns of the spinal cord is known to produce muscular contracture as a prominent symptom, probably because the inhibitory influence of the brain upon the reflex excitability of the spinal cord is arrested, or because the sclerosis directly excites the motor apparatus of the cord. The peculiar deformities produced by post-paralytic contracture and the eccentricities of gait and posture exhibited by patients suffering from tetanoid paraplegia (lateral spinal sclerosis) are illustrative of the diagnostic value of tonic muscular spasm in the course of some spinal affections.

Respecting the effects of electrical treatment of spasm, I am convinced that in some cases many methods must be tried without benefit before the right one is discovered. I have occasionally had brilliant results follow some particular method, and subsequently I have been utterly disappointed when it was tried upon some other patient with identical symptoms.

I think that in this class of subjects more depends upon your success in ascertaining and removing the cause than upon any electrical applications (valuable as they may be as adjuncts). The correction of an optical defect by glasses, the relief of ocular insufficiency by tenotomy or prisms, the operation of circumcision, the mechanical relief of a displaced womb, and many other such procedures, form the basis of an absolute cure in many cases which have been otherwise treated unsuccessfully. This fact is too often disregarded.

Electrical currents may be made to act upon these cases (1) as a sedative (chiefly the action of the anode and static insulation); (2) as a stimulant (the action of the cathode, the static spark, or faradism); (3) as a counter-irritant; (4) as a check to the progress of some peripheral or central morbid state (catalytic action); and (5) as an agent for the destruction of some neoplasm, induration, etc. (electrolytic action), or as a cautery.

I have lately come to regard static electricity (franklinism) as more generally applicable to spasmodic conditions (hysteria, torticollis, blepharospasm, tremor, contracture, etc.) than either faradism or galvanism. It seems, in my experience, to act more promptly, and to produce more lasting results, than the methods more commonly recommended by authors. I would advise those of you who decide to purchase a static machine to try the effects of insulation, the "electric wind," and the indirect spark (as the circumstances may indicate) faithfully before you resort to galvanization or faradization. If good results are not obtained, you can easily substitute for it the other forms of treatment at a later date. I should never regard any case as hopeless until it had been thoroughly tried (after all reflex causes had been removed). I have cured several severe cases of tonic spasm of the muscles of the neck in a few sittings by means of the indirect spark, and relieved many cases of suffering from other forms of spasm in a short time.

In EPILEPSY, the employment of galvanism alone has never, to my knowledge, resulted in a complete cure, although some decided benefits have been reported from its continued use. There is, to my mind, a close relationship in many cases *between epilepsy and ocular defect*, to which I shall call your attention hereafter. This element in the causation of epilepsy certainly merits attention. When all defects in the visual apparatus have been corrected (in case such exist), or when other reflex causes (such as phimosis, for example) have been relieved, galvanism and static electricity may become valuable aids in controlling the subsequent convulsive attacks. Latent hyperopia, astigmatism, and insufficiency of any of the muscles of the eyeball may (and, in my opinion, often do) excite epileptic seizures. It is absurd to expect of electricity, or any other therapeutical agent, curative results when so important a source of irritation of the central nervous system is allowed to remain uncorrected.

Rockwell's method of employing "central galvanization" in epilepsy does not, to my mind, equal in beneficial effects the use of static insulation and the drawing of indirect sparks from the neck and back of the patient. It is my custom, however, in some cases to employ both of these procedures, each being used alone during alternate weeks for a period of two or three months with daily sittings.

In CHOREA I have obtained the best results with static insulation and sparks.

My previous remarks respecting the relationship between defects in the organ of sight and epilepsy apply with equal force to this disease and all other types of functional nervous derangements. I shall discuss this subject more in detail later in the course when functional nervous diseases are being considered.

If galvanism is employed, it is best to subject the muscles affected with spasm to the action of the *anode*. The

prognosis will depend somewhat upon the duration of the disease. The earlier you begin electrical treatment, the greater is the prospect of cure (provided all sources of reflex irritation have been successfully removed).

My experience with faradism in the treatment of chorea has been somewhat limited; but the results obtained by me have not been so satisfactory as with static electricity.

In facial spasm (histrionic spasm) good results are occasionally obtained by following the plan of treatment suggested in connection with chorea; but treatment of the facial nerve alone is seldom satisfactory. I have one case at present under treatment, however, in which I have thus far had little, if any, success in my attempts to control the spasm. It is a case of long standing, and is therefore more rebellious to treatment than if it were not chronic. The patient has an ocular defect which it is difficult to correct perfectly.

In these cases I have obtained the best results by subjecting both the cortical centers for facial movements and the nerve itself to stabile applications of the anode (the cathode being placed on the breast-bone), and by treating the nerve at intervals with static sparks drawn from the affected portions of the face. The electrode for the head should be large. The duration of each daily sitting should not exceed five minutes.

Nystagmus and blepharospasm belong to the choreic type of diseases, and are best treated by electrical currents, provided they are seen before the condition has become chronic. The prospect of a radical cure steadily becomes less as time elapses. If static currents are employed, wooden tips to the electrodes should be used. I usually treat these cases as if the seventh nerve were involved in all of its branches. Sometimes it is well to place the anode upon the mastoid process and the cathode upon the closed eyelid. The current should be very weak at first; should be gradually increased until faint flashes of light are perceived; finally, it should be again decreased to the faintest perceptible point.

Torticollis, or wry-neck, when subjected early to static sparks or strong faradization, may often be cured very rapidly. Interrupted galvanic currents are also of material benefit in some cases.

The spinal accessory nerve is usually the one which is at fault. A rheumatic origin may often be detected. If so, judicious medication will tend to hasten the cure.

Some cases of wry-neck are associated with symptoms of paresis. These have, as you might suspect, a more serious prognosis. Electrical treatment will prove, as a rule, only palliative. Too often organic changes have already occurred in the spinal accessory nerve, the spinal cord, or the vertebræ. The duration of treatment should extend over a period of months.

Spasmodic asthma may often be benefited by galvanism of the neck. I have previously described the steps of this procedure. Its beneficial effects are probably due to changes induced in the vagi. Drawing of indirect sparks (by means of the static machine) from the anterior and posterior surface of the chest has proved, in my experience, an admirable preventive against such attacks.

Some patients have assured me that they experienced a sense of great comfort after each sitting, and that the frequency of the paroxysms of asthma has been perceptibly modified by them. My experience in the electrical treatment of these cases is as yet somewhat limited; but I am inclined to believe that greater benefit can be derived from it than from internal medication. Certainly it is worthy of a more extended trial, as an adjunct, if deemed wise, to other remedial measures, or as a substitute for them.

In tetanus (both of the traumatic and idiopathic varieties) two cases of cure have been reported by Mendel, of Berlin. He employed galvanization and subjected the muscles affected with spasm to the stabile influence of the anode, the cathode resting over the spinous processes of the vertebræ. The applications were continued for fifteen minutes, and the currents employed were mild ones. Bartholow suggests, when speaking of these cases, that the effect of these applications was probably due "to the influence of the currents upon the sensory nerves, thus lessening the intensity of the reflexes." The cures were complete in about ten days.

Personally, I have not as yet been able to test the effects of the different forms of electrical currents upon a case of tetanus. To my mind, it would be very interesting, however, to observe the effect of static insulation and static sparks upon the spasms which occur paroxysmally in this disease. It is well known that this agent exerts a remarkable effect upon contracture of muscles. Thus far, to my knowledge, it has never been tried in tetanus.

Sneezing, hiccough, and coughing are spasmodic efforts of a reflex character. Occasionally they become distressing from their persistency. They may, in some instances, be relieved by faradization of the epigastrium, galvanization of the neck, and static electricity. De Watteville reports some curative effects of galvanization of the nasal mucous membrane in chronic cases of persistent sneezing.

ELECTRICITY IN DISORDERS AFFECTING SENSORY NERVE-TRACTS.

The discovery that different bundles of fibers which help to compose the substance of the spinal cord serve to convey sensory impulses only, and the later researches which have also been made respecting the paths of conduction specially prepared for sensations of pain, touch, temperature, pressure, the muscular sense, visceral sensations, etc., have a practical bearing upon both diagnosis and treatment.

Clinical observations go to show that, of the separate and distinct types of sensation enumerated, some may be partially or completely destroyed by diseased conditions without impairing the others. Thus, for example, a patient under certain conditions may be able to exercise his sense of touch with normal acuteness and yet be rendered absolutely insensible to pain; again, he may be unable to discriminate between degrees of heat or cold (provided the tests do not produce pain), although he retains unimpaired sensory faculties in all other respects. We are, therefore,

forced to recognize a variety of types of anæsthesia as presenting themselves for diagnosis and treatment.

The sensory functions may be either increased (*hyperæsthesia*) or diminished (*anæsthesia*).

Either of these states may be of *organic origin* (by which we mean that structural changes in the nervous tissues accompany them), or of purely *functional origin*, in which case no structural changes can be shown to exist. Examples of the former are found in connection with central lesions (those of the brain or spinal cord), and with peripheral lesions of the sensory nerves or the organs of special sense, while examples of the latter are frequently encountered in connection with hysterical conditions, neurasthenia, cold, injury, imperfect capillary circulation, rheumatism, neuralgia, and many other morbid conditions.

In all forms of sensory disturbance the removal of the cause constitutes in many cases the basis of a cure, and the treatment will necessarily be modified by the causal indications.

Many suggestions which have previously been offered respecting electrical applications to the brain, spinal cord, and peripheral nerves are applicable alike to sensory as well as motor disorders when due to organic changes; hence, when this fact is borne in mind, it will be unnecessary to repeat what has already been given you.

In the treatment of ANÆSTHESIA nothing can surpass in its results the daily rise of the *wire brush* for about ten minutes over the regions affected. This form of electrode should be applied dry and with the *secondary coil* of a faradaic machine. The stabile electrode should be well moistened and pressed closely in contact with some distant point.

If *trophic disturbances* co-exist with anæsthesia, I have found the "combined current" (galvano-faradaic) to be more efficacious than faradism alone.

Static sparks and static insulation often act wonderfully in functional nervous diseases.

Static *insulation* has been previously described. It should be administered daily for from ten to thirty minutes.

If the "*indirect spark*" is employed (see Fig. 30), the length of the spark should be sufficient to be perceptible to the patient, and the duration of the application should seldom exceed five minutes. It is well to administer a fusillade of sparks to the region of the spine after each insulation, in case the sensory disturbances are dependent upon hysteria or neurasthenia.

I seldom employ the "*direct spark*" (Fig. 3) except in the treatment of organic disturbances of sensation or motion.* This form of administration should be used with extreme caution if the generating machine is a powerful one.

The "umbrella" electrode furnishes an agreeable and effective method of concentrating static electricity to the head of the patient. The sensation is one which resembles that of a strong breeze circulating through the hair.

HEMIANÆSTHESIA (whether of cerebral or spinal origin) is often benefited by cutaneous faradization of limited portions of the area affected—a point first observed by Vulpian, who employed this method with marked success.

TROPHIC DISORDERS may occasionally manifest themselves, often in the skin, nails, hair, and muscles, when sensation is markedly affected. One such case (suffering from locomotor ataxia) was lately placed under my care. The fingers of both sides were almost destitute of sensibility to pain, and tactile sensation was impaired. The nails were thickened, loosened for half of their length, and deeply pigmented (as if stained with iodine). The terminal phalanges were "clubbed," the nails being bent almost into a semicircle. The skin was thickened and very hard under the loosened nails. The "combined current" (galvano-faradaic) with a wire-brush electrode caused decided improvement within a few weeks.

NEURALGIA (when of idiopathic origin) is more successfully treated to-day by electricity than by any medicinal agent. In many instances it is cured in a few sittings.

It is well to bear in mind, however, the fact that neuralgic pains are very often symptomatic of causes more or less remote from the affected nerve, and that a permanent cure is impossible in many instances as long as that cause actively exists. Defective teeth, morbid processes in the bones, pressure upon a nerve, organic changes in the nerve itself, toxic diatheses, rheumatism, gout, reflex irritation from the eye, uterus, digestive tract, ovaries, etc., cardiac and pulmonary disorders, and many other morbid conditions, may be enumerated as among the exciting causes of neuralgia.

Respecting the electrical treatment of neuralgic pains (*per se*) the following deductions may prove of some advantage to you:

1. If points of tenderness to pressure (*puncta dolorosa*) exist along the course of the affected nerve or its branches, it is well to subject them to stabile galvanic applications of the anode, the cathode being placed at a neutral point.

2. The anode should be made to cover as large an area as possible.

3. The duration of the sitting should not exceed five minutes, save in exceptional cases. The sittings may be repeated several times a day if necessary.

4. As a rule, it is unwise to break the current. In obstinate cases the current may occasionally be reversed, without changing the poles, by means of the commutator.

5. Faradization of the nerve and the use of the wire brush upon the skin have been recommended when galvanism proves unsuccessful in arresting the pain. It should not be used (in my opinion) until galvanism has been thoroughly applied.

6. It is well in obstinate cases to direct the applications of galvanism to the central origin of the affected nerve, as well as to its peripheral distribution.

* Since these lectures were delivered I have at last perfected an improvement upon the Holtz static machine, upon which I have been working for some time, and I have had one of this pattern built for my own use by Waite & Bartlett, of New York. I intend soon to present this improvement formally to the profession with appropriate cuts and a description of the various modifications made. My own machine after this model gave me a ten-inch spark during a "muggy" day in July, when most static machines would produce but a feeble spark. It is the most effective instrument of the kind which I have yet seen. It consists of nine twenty-four-inch glass plates, six of which revolve. All the joints of the case are hermetically sealed with soft rubber.

7. Static electricity often produces marvelous results in neuralgia. I have more faith in it as a cure for sciatica than in any other remedial agent. It should be applied (by the "spark" method) over the affected nerve. One sitting has, in my experience, frequently arrested severe pain. It gives immediate relief, in most cases, to muscular rheumatism also, and to lumbago. Sufferers from muscular and neuralgic pains are perhaps as frequently encountered by the physician as any class, and static electricity should highly recommend itself to your confidence for such cases. The expenses of the outfit, and the fact that the machine is too large for transportation, will probably prevent its general use by the profession; but, until its effects upon a patient have been tried, I would caution you against expressing an unfavorable opinion, even if galvanism, faradism, and medicinal treatment have proved powerless to relieve the suffering.

8. The operation of electro-puncture of a nerve for the relief of neuralgia has proved of benefit in the hands of some neurologists; but it is an operation which, if injudiciously employed, will produce electrolysis, and serious results may follow its use.

9. The electrical treatment of various other forms of pain is similar to that of neuralgia. The judgment of the physician should be exercised regarding the position and size of the electrodes, the variety, strength, and duration of the current employed, and various other minor points suggested by the condition of the subject.

10. *Visceral neuralgias* (as, for example, the conditions known as hemicrania, migraine, gastralgia, enteralgia, hepatalgia, etc.) are often relieved by electricity, irrespective of the reflex or constitutional condition which induces the morbid state. The removal of the exciting cause, however, will greatly assist in making the cure a radical one. I have long taught in my lectures that I had yet to encounter a patient who had suffered for years from migraine who had not some defect in the eye or its muscles as an exciting cause. Experience leads me still to strongly assert this as my conviction. The same cause is very frequently manifested by paroxysms of spinal pain—peculiarly so at two points, viz., between the scapulæ, and at the junction of the last lumbar vertebræ with the sacrum.

The currents which act best upon these cases are the galvanic and static. I have in two instances employed faradism in gastralgia with good results, but I regard it as inferior to galvanism or franklinism.

In treating the abdominal viscera by galvanic currents, one rheophore may often be attached with advantage to a rectal electrode, and the other to a large electrode placed over the organ to be influenced. I do not believe that polar effects are to be particularly aimed at. In some cases, an occasional substitution of the "combined current" (galvano-faradaic) for galvanism makes the improvement of the patient more rapid.

Static applications to the abdomen are best made by employing indirect sparks of about two inches in length. Long sparks are not borne well by sensitive subjects. If patients are subjected to static insulation alone for twenty minutes daily, or to the electric spray over the abdomen, relief is often afforded and the application is painless. The clothing need not be removed in making applications of franklinism by either of these methods—a point which renders the treatment particularly agreeable to ladies.

(*To be concluded.*)

Original Communications.

ERYSIPELAS OF THE LARYNX AND PHARYNX.*

By D. BRYSON DELAVAN, M. D.

Since the remarkable and exhaustive thesis of Cornil, which appeared in the "Archives générales de médecine" in 1862, little new knowledge has been advanced, either in the pathology, the clinical features, or the treatment of this affection. Morell Mackenzie, in his excellent *résumé* of the subject, tells us that erysipelas of the mucous membrane of the pharynx and larynx is, pathologically, similar to the same malady when situated on the skin, and that it occurs either primarily or by extension from the face along the mucous tracts of the mouth, nose, or ear. Its causes are the same as those which give rise to it when situated upon the external parts of the body, although it has been most often observed in the course of general epidemics of the disease. Of eighteen patients seen, in whom the pharynx was affected, fifteen were under the age of thirty, and two thirds were females. Again, on inspecting the pharynx, the appearance of the mucous membrane when affected with erysipelas differs considerably according to the form of the disease which is present; the local phenomena are generally very different from those of tonsillitis, but often can not be distinguished from those of simple inflammation of the part. Cornil makes three divisions of the malady, viz.: (1) erysipelas with simple redness; (2) erysipelas with phlyctænulæ; and (3) erysipelas terminating in gangrene. Erysipelas most commonly reaches the larynx from the pharynx, but the former organ may be primarily affected while the pharynx remains healthy. According to one author, quoted by Mackenzie, the disease may extend still farther down the respiratory tract. In cases which come under the first division the diagnosis must remain doubtful except in cases where the throat lesion is accompanied by manifestations upon the skin.

As to the prognosis, the dictum of Hippocrates—namely, "When erysipelas extends from within outward it is a favorable symptom, but when it removes to the internal surfaces it is a deadly one"—has been confirmed by modern observation. In nine cases analyzed by Cornil where the face was first attacked, seven deaths occurred; whereas, in nine other instances where the enanthem preceded the skin eruption, seven recoveries took place. Mackenzie states that he has seen but four cases in the whole course of his practice.

* Read before the American Laryngological Association, June 24, 1885.

From the foregoing statements it would appear that the disease in question has been so long ago recognized, and its nature is so well understood, as to render its introduction at the present time unnecessary. In searching for the records of authentic cases in available American literature, however, we are surprised to find but a single instance in which the disease has been described, namely, the case reported last year by Dr. T. A. De Blois. The case reported by Dr. William Porter, of St. Louis, was that of an Englishwoman whom Dr. Porter attended while residing in London. Whether it is more rare in this country than in Europe, or whether, on the other hand, it is either allowed to pass unrecognized or else regarded as a simple and ordinary complication of the general affection unworthy of special mention, it is impossible to say. That the condition is an important one no one will question, while the very general nature of the treatment suggested proves that additional light upon the subject is greatly to be desired. With the intention of awakening a sufficient interest in it to secure a more general recording of such cases as may arise, the following histories are presented:

Edward Smith, aged twenty-nine, of robust appearance, had always enjoyed good health. On February 10, 1883, two months after admission to the workhouse, applied at the dispensary, complaining of chilliness, general muscular soreness, and pain in the bones. There was slight soreness of the throat, and pain in deglutition, which he stated he had first felt upon the right side. The tonsils were congested and slightly enlarged, particularly the right.

February 11th, 12th.—Felt much worse and experienced more dysphagia. He also complained of a feeling of dryness in the nasal passages and inability to breathe through the nose. Described the nasal condition as being like a "cold in the head." The pulse was somewhat accelerated, and there was a slight rise of temperature.

14th.—Was transferred to the hospital, all of the above symptoms being exaggerated. Temperature 102°, pulse 96, respirations 27. Tongue and teeth covered with sordes; tonsils and pharynx deeply congested. At this time also a herpetic eruption appeared on the face, below and to the outer side of the angle of the mouth.

15th.—On the morning of this day an erysipelatous redness, attended with swelling, appeared upon the upper lip, adjoining the alæ of the nose, and fading off upon the cheeks. There was also severe pain in the back of the head and the neck. The appetite was good, and there was little malaise. The temperature, however, was 104°, pulse 96, respirations 24.

17th.—The swelling and redness had extended to the margin of the hair, and had invaded the neck. The face was covered with blisters. The pulse was running and intermittent at 80, and the tongue black and dry. Severe pain still continued in the back of the neck.

18th.—Did not appear to suffer much pain. Erysipelas not extending.

19th.—Patient fell into a semi-conscious condition, from which it was impossible to arouse him, and questions put to him met with no response.

21st.—Semi-consciousness continued, but the patient began to be very restless and delirious. His hands were kept in constant motion, and it was almost impossible to keep him in bed. The facial swelling had subsided, and exfoliation of the epidermis had begun. The tongue was still black and thickly coated. The pulse and temperature were normal.

22d.—Patient was more rational and able to answer questions.

23d.—Was again slightly delirious, constantly sitting up in bed and throwing off the bedclothes, and fighting any one who came near him. Temperature 97°, pulse 50, respirations 21.

24th.—The delirium became active and of an hilarious character, the patient singing, shouting, and constantly arranging the bedclothes, and imitating the actions of the ward attendants. The condition of the tongue had cleared somewhat, and the appetite had returned.

26th.—Patient was slightly irrational. Tongue clean; exfoliation of epidermis of face, neck, and ears progressing. Temperature and pulse normal.

March 3d.—Delirium entirely gone. Exfoliation almost complete. Hair began to fall out. During the whole illness there was obstinate constipation.

12th.—Patient was discharged, apparently cured.

On the morning of March 16th, however, the attention of the house surgeon was called to Smith on account of his wild appearance and strange actions. He was wandering aimlessly about the corridors, and seemed sullen and morose. This continued until the morning of the 18th, when he was transferred to the hospital again. He would pay no attention to those about him, answered questions a long while after they were put to him, imagined that his fellow-workmen were trying to annoy him, and that every one was plotting against him. While in the hospital he had delusions of a religious character at times, and at other times he imagined that some one whom he did not know was constantly urging him to the performance of a variety of strange actions, and he believed that he must obey. He was treacherous, and would strike at the attendant whenever a good opportunity presented. His nights were restless and sleepless, and the constant hallucination of an outside impelling influence kept him busily engaged, while he would hide under the bed, fix himself in various positions in bed, arrange the bedclothes, and at times sit and stare at some one object for half an hour. If given something to do, he did it well, and while busy was happier and more satisfied to stay in the ward, but, when unemployed during the day, would constantly walk up and down, watching an opportunity to escape. During the five days he remained in the hospital he had no rise of temperature, his pulse was somewhat accelerated and weak, and his appetite good. As soon as his transfer could be effected, he was sent to the Insane Asylum at Ward's Island, where, when last heard from, he still remained.

The following case occurred in the wards of the New York Almshouse Hospital during the service of the writer in the spring of 1882. Unfortunately, careful notes were not taken at the time, and it will, therefore, be possible to report only as much as can be given from memory. The patient was an aged pauper of about seventy years, large, somewhat stout, and decidedly rheumatic. She was attacked with what at first seemed an acute laryngitis. The disease, however, spread rapidly in both directions, involving both the lungs and the pharynx, producing in the former distinct and widespread broncho-pneumonia, and in the latter an intense congestion. The mucous membrane here was also œdematous, and of a dark, purplish color. So peculiar was its appearance, and so threatening the extent of the œdema, that a laryngoscopic examination was made to ascertain the probable necessity for tracheotomy. Although in a state of general tumefaction and of the same dark color as the pharynx, there was an ample rima glottidis, but marked hoarseness of the voice. The constitutional symptoms were slight, considering the nature and severity of the attack. By degrees the inflammation extended from the pharynx to the lips, whence, apparently having received a fresh impetus, it

spread over the face. Meanwhile, the co-existence of diarrhœa, mild delirium, and continued high temperature rendered the general condition grave. This period marked the height of the attack. The lungs were first to improve, and the disappearance of the pneumonia was followed by a subsidence of the laryngeal and pharyngeal inflammation and a marked improvement in general. Strange to say, as desquamation occurred in the face and neck, the erysipelas extended, by slow degrees, over the whole body, the march being slow, the general symptoms mild, and no great extent of surface being involved at any one time. At the end of several weeks this process was completed by involvement and subsequent desquamation of the legs and feet. The patient recovered.

The case first related would, if classified according to the method of Cornil, belong to division number two, since it was decidedly severe in its nature, and the presence of phlyctænulæ, although not mentioned in the history by my house surgeon, was distinctly observed by myself. The features of the case which especially distinguish it are, first, the occurrence of the disease idiopathically in a patient who, so far as could be learned, had not been exposed to any erysipelatous infection; secondly, the distinct limitation of the disease to the tonsil for a period of three days; and, thirdly, the marked cerebral disturbance and subsequent insanity.

No especial cause of irritation was apparent in the tonsil; the man had been to all appearances unusually strong and healthy, and the sanitary condition of the premises was at the time tolerably good. The limitation of the inflammation and its absolutely benign appearance at the beginning of the attack were sufficient to disarm suspicion as to its true nature, and entirely out of harmony with the subsequent severity of the symptoms. By far the gravest of these was the effect of the disease upon the brain. So far as could be ascertained, the patient had never before manifested any sign of mental aberration. His insanity, therefore, bore such a distinct relation to the attack that, beyond question, the one was intimately associated with the other. Of course, it is by no means unusual for facial erysipelas of the ordinary type to be complicated with delirium and coma, and even the more serious cerebral symptoms indicating meningitis, so that it is not surprising to find it developed by the form under special consideration. The mechanism of this metastasis, however, is a matter of as much interest as it is of uncertainty. Formerly it was explained as being a localized manifestation of a general morbid condition. At present believers in the germ theory will probably maintain that it is due to an incursion of the bacillus of erysipelas from the frontier regions to the interior. Before accepting the foregoing it seems but just to call attention to the possibility of *direct extension* of the disease from the deeper layers of the olfactory region, and through the cribriform plate of the ethmoid bone, to the meninges. Improbable as this may appear, it is still worthy of notice, since the influence of inflammatory conditions of the middle ear and of the frontal sinus in exciting cerebral complications is well attested. By whatever process it may have occurred in the case under consideration, there was established, without doubt, a meningitis, at first acute. Subsequently the acute attack passed into the chronic form, presenting the symptoms of this condition typically described toward the end of the history.

Case number 2 is more after the usual course of the disease. The patient was old, feeble, and lithiatic. She was housed in a crowded, ill-ventilated hospital ward, in which, although there may not actually have been another case at the time, erysipelas was never, for any great length of time, absent.

In an article published in the "Rivista Clinica e Terapeutica," No. 1, 1885, Dr. F. Massei, of Naples, endeavors to prove, from a study of thirteen cases, that the so-called primary œdema of the larynx, or phlegmonous laryngitis, corresponds clinically to a localization of erysipelas in the larynx. He describes the objective symptom of the disease as being a marked swelling, which, beginning at the epiglottis, extends to the mucous membrane of the arytænoepiglottic ligament and the inter-arytænoid space, causing dyspnœa, dysphagia, and aphonia. The onset is generally sudden, and the laryngoscope shows such intense swelling that the interior of the larynx can not be demonstrated. Blood and pus are occasionally poured forth from spontaneous rupture of the mucous membrane. Often the swelling migrates, decreasing on one side and increasing on the other. The prognosis is, either recovery or else death by asphyxia or pneumonia.

Massei considers the disease erysipelatous for the following reasons:

1. Its rapid development and its tendency to wander, as well as its predilection for parts in which the lymphatics are abundant.

2. The constitutional symptoms which resemble those of erysipelas.

3. Its want of resemblance, from its migratory character, to the ordinary forms of laryngitis.

4. The tendency of the disease to extend to the lungs, and, finally, its occurrence during the course of epidemics of erysipelas.

He concludes:

1. There is a primary erysipelas of the larynx.

2. Many cases reported as primary œdema of the larynx are really cases of erysipelas; this occurs more commonly than is generally supposed.

3. There are two forms: in the first the local manifestations precede the general; in the second they close the scene.

4. The best methods of treatment are applications of cold, scarification, and, finally, if asphyxia threatens, tracheotomy.

It will be seen that Massei's observations relate solely to the larynx. Although somewhat general in their nature, they are given as supplementing the views of the writers quoted above, while the recommendations as to treatment still leave much to be desired.

The writer is certain that, as house surgeon ten years ago in a large public hospital in which the erysipelas pavilions formed an important part of the service, both laryngeal and pharyngeal cases were occasionally presented. Unfortunately, their real nature was not then recognized, and in the lapse of time which has since occurred the recol

lection of the facts connected with them has become too indistinct to enable him to refer to them with any confidence or accuracy.

DISCUSSION.

Dr. De Blois said: My case, to which the reader has just referred, closely simulated follicular tonsillitis, and I treated it as such for twenty-four hours. The pharynx was involved in the inflammatory process, and both tonsils were equally affected. On the next day it appeared to have extended to the nasal cavities. There was a discharge from the nose, and what was much like a diphtheritic membrane in the posterior nasal cavities. There was no appearance on the face of any skin affection. There was some malaise, but the patient did not have a higher temperature than would be usual in the course of a severe tonsillitis. On the fourth day, when the disease passed on to the nasal cavities, the inflammation of the tonsils was somewhat improved. Later erysipelatous redness appeared over the bridge of the nose. The internal manifestations meanwhile became somewhat better, and the case progressed to a very severe attack of facial erysipelas. She subsequently recovered. The point which I wished to bring out was, the difficulty of diagnosis.

Dr. Rice.—It would seem strange that erysipelas of the larynx and pharynx should be such an infrequent disease when the conditions are so favorable to its development. Cases of facial erysipelas are very common when at the same time the patient is suffering with extensive ulcerations of the nose and pharynx, which, we should suppose, would invite an extension of the disease to this locality. And yet this is a rare occurrence. Ulcerations on the cutaneous surface are almost always attacked; on the mucous membrane it is the exception. I am convinced that erysipelas of the larynx does exist where a diagnosis is not made. I remember in the erysipelas wards of Charity Hospital there were two cases (which were called "œdema glottidis") where tracheotomy was done; the inflammation here was probably of an erysipelatous nature.

Dr. Roe.—An interesting case of erysipelas of the larynx and pharynx came under my observation about a year and a half ago, in a lady, about thirty-seven years of age, of a nervous sanguine temperament. She was under treatment for naso-pharyngeal catarrh. The attack seemed to be due to exposure during a slight fall of snow, in the course of which she rubbed her face with snow. Within six hours afterward she had well-marked facial erysipelas. This went on its usual course, but soon assumed a severe type. Within thirty-six hours afterward she had delirium. The erysipelas extended to the neck and into the pharynx, also into the larynx, causing marked œdema of the larynx and pharynx, so that there was severe dyspnœa for about twenty-four hours. One night I remained in the house expecting to have to perform tracheotomy before morning. I used the usual course for erysipelas—*i. e.*, mild alkaline sprays, with a little alcohol—which seemed to have a very quieting and soothing effect, and soon the erysipelas began to subside in the face and gradually in the larynx and pharynx. In about four days the symptoms in that region disappeared. These cases must be unusual, as Dr. Delavan has said, although often attributed, probably, to other causes.

Dr. Cohen.—Having seen the admirable effects of the hypodermic injection of hydrochlorate of pilocarpine in facial erysipelas in hospital practice, it occurs to me that it would be an admirable method of treating these rare cases. Its action in doses of one sixth of a grain is very prompt.

Dr. Delavan, in closing the discussion, said: There seems to be no reason why any inflammatory condition of the pharynx—such as diphtheria, follicular tonsillitis, or peritonsillar abscess—should not excite an attack of erysipelas, so that a case beginning as a simple attack of one of the former affections may result in the latter. With regard to the use of pilocarpine, I have found the dose recommended to be, in some cases, excessive, and would urge the employment of this potent drug in smaller quantities, one twentieth of a grain often being sufficient.

REFLECTIONS ON THE ÆTIOLOGY OF THE SIMPLE INFLAMMATORY AFFECTIONS OF THE UPPER AIR-PASSAGES.*

By JOHN N. MACKENZIE, M. D.,
BALTIMORE.

"*Ille bene curet, qui bene morborum causas agnoscit.*"—Celsus.

In view of all that has been said and written concerning inflammatory conditions of the naso-laryngeal tract, it is amazing to find what little advance has been made toward a more rational conception of the causes that underlie diseases of such prevalence and wide distribution.

It is not the purpose of the present communication to treat in an exhaustive manner the conditions under which inflammation of the upper air-passages develops, but simply to offer for your consideration a few general observations and desultory reflections, which, I trust, through the discussion which follows them, may serve to throw new light upon the subject, and stimulate others to more perfect and fruitful research.

At the outset of our inquiry we should divest the mind of the idea that the pathology of nasal and laryngeal disease is an isolated pathology. The eruption of catarrhal processes in the respiratory tract is governed by the immutable laws that condition the development and course of inflammation in general, and the rational interpretation of nasal and laryngeal affections presupposes, therefore, the application of general pathological principles to the peculiar conditions which the anatomical and physiological functions of the structures involve. Above all, we should remember that peculiarity of structure is not anatomical isolation; we should remember the correlation of organ and organ, the sympathy of tissue and tissue which make up the perfect physiological life of man. In looking upon the subject from the high vantage ground of general pathology and laws of health, we may, therefore, more readily apprehend the rôle which external and internal influences play in the evolution of nasal and laryngeal disease than if we viewed the same from the level of a narrow specialism or from the standpoint of the mere empiric.

I. Inflammation of the upper respiratory tract, either in its entirety or localized in its individual parts, is a disease of the human race which has existed from the remotest period of historic time.

II. As the chief predisposing and exciting causes of the affection have been in operation for all ages, it follows, therefore, that its origin is coeval with the birth of man.

III. The evolution of nasal, pharyngeal, and laryngeal inflammation in a given locality is, in all probability, a part

* Read before the American Laryngological Association, June 24, 1885.

of its geological history, and goes on *pari passu* with its varying meteorological conditions. Hence the geographical limits of the disease have varied with the different epochs of the earth's formation.

The elaboration of the above propositions involves an inquiry into the origin, the predisposing and exciting causes of nasal, naso-pharyngeal, and laryngeal inflammatory affections, and their distribution over the surface of the earth.

Origin.—In the third book of Plato's "Republic" the philosopher tells us that the names of catarrhs were unknown to Homer, and only came into use in the age of Socrates. This assertion of the Grecian sage has been made the groundwork of the thesis that catarrhal diseases are the products of civilized life, and furnishes, among other things, the basis of the Schneiderian argument that these affections are born of luxury and ease and of the general degeneracy of mankind.

It is doubtless true that a marked tendency to catarrhal diseases belongs to modern man from the accidents which pertain to his environment, and that as civilization awakens morbid conditions unknown or rarely met with in the savage state, so the disposition to inflammatory troubles of the upper respiratory passages may be encouraged by transmitted vices and the enervating surroundings of modern social life. At the same time it is reasonable to assume that, as the chief causes productive of acute and chronic inflammation of the naso-laryngeal tract have been in operation from the remotest times, the origin of the affection is therefore traceable to that of man himself.

The very etymological derivation of the word *coryza* carries us back through the dialects of the Hebrews, Arabians, Chaldeans, and Assyrians to the time when history emerges from fable; the attention paid by the most ancient exponents of medical art, of which we have any record, to inflammatory states of the nose and throat, implies the former frequency of these affections, while the derivation of the terms *angina* and *cynanche*, and the early origin of bronchotomy, point to their recognition of the most dangerous forms of laryngeal disease. The classification and correct clinical history of disease is, moreover, a process of gradual evolution, and, in view of the confusion which reigned among the latter-day nosologists in regard to laryngeal affections, it is not surprising that in the most ancient records of medicine we fail to find that exact anatomical division of catarrhal affections which was the natural outcome of subsequent more advanced anatomical and physiological investigation.*

Inflammatory disorders of the upper respiratory apparatus may be the result of a host of conditions external to the body which arise from man's relation to the outer world, may proceed from agencies within the organism, whose sphere of operation embraces the system as a whole, or is limited to its individual parts, or, finally, they may be the outcome of defective anatomical and physiological relations —of absence or abrogation of activity in the respiratory structures themselves and in the functions and forces under their control.

The discussion of the causes proceeding from the first source leads naturally to the consideration of the geographical distribution of the affection.

Geographical Distribution.—*Predisposing and Exciting Causes.*—The geographical limits of nasal and post-nasal catarrhs are as yet imperfectly defined, but it is highly probable that they bear a close relationship to the distribution of catarrhal affections of the respiratory organs in general over the surface of the earth. Thus it may be laid down as a rule that catarrhal inflammation of the nasal passages is much more frequently met with in cold- than in warm countries, in high than in low latitudes. The observations of travelers and explorers show that the nearer we approach the equator the less prevalent become affections of the respiratory apparatus, while in the temperate zone they are the most common of all diseases, and preponderate in these regions according to the proximity of the individual localities to the polar circle. In the temperate zones of both hemispheres catarrhs are more frequently met with in those places which lie between the isothermal lines of 18° and 4° (Seitz). The prevalence of these affections is related not only to the geographical position of a given country, but also to its elevation above the surface of the sea; the higher above the sea-level, the more marked the tendency to catarrh (Hirsch, Seitz), a fact partially explicable by the analogy of natural conditions or meteorological relations between high mountainous regions and those of the frigid zones. In every zone the geographical distribution of the complaint depends, other things being equal, apparently mainly on climatic influences. *In those countries where extremes of temperature follow each other in rapid succession, where the thermo- and barometrical fluctuations are most sudden and occur with the greatest frequency, and where the material composition of the atmosphere is continually changing, catarrhal affections of the naso-laryngeal tract are most frequently met with. The appearance of the disease seems to depend not so much upon the degree of heat or cold as upon the rapidity and intensity of the change from the one to the other.* In warm countries, coryza and allied affections most frequently prevail during the sudden cooling of the atmosphere by rain-showers, electrical disturbances, or when the heated condition of the atmosphere alternates with dampness and chilliness of the nights. In a similar manner the more or less sudden passage from a dense to a rarefied atmosphere, as in balloon and mountain ascensions, favors the development of nasal congestion and inflammation.

The influence of season in the production of nasal inflammation is simply a part of the greater question of temperature mutations, and will therefore vary with the period of greatest temperature changes in a given year. While spring and autumn furnish perhaps the largest percentage of nasal and laryngeal catarrhs, the coryza which appears in the summer months, when the air is suddenly cooled or altered by electrical and other disturbances, yields to none in the severity of its symptoms and course.

Of all conditions of the atmosphere the most pernicious

* Hence we find in the Ayur Véda affections of the larynx confounded with those of the palate and pharynx, and among certain of the Hippocratic and Galenic schools the names pharynx and larynx are occasionally employed as convertible terms.

to the nasal, and consequently to the pharyngo-laryngeal mucous membrane, is perhaps its saturation with aqueous vapor. Its influence is much more potent in the production of nasal inflammation than that of cold. Indeed, the injurious effect of the latter, *per se*, has been grossly overrated, and, if we examine the subject closely, we will find that there are many other agencies at work whose operation explains the prevalence of these affections in the frigid zones and in the regions of perpetual snow. *The effect of moisture is furthermore intensified by its association with intense cold or oppressive heat.*

It is impossible to overlook the rôle of the *winds*, especially when associated with brusque thermometric changes, in the spread of coryza and allied affections. The strata of air of different temperatures which they bring with them, the moisture, dust (germs?), and, in some instances, the physical shock and pressure which they exert upon the body, as well as the rapidity of evaporation of the cutaneous and respiratory transpiration which they occasion, are powerful agents in the determination of naso-laryngeal catarrh. The terrible effect of the hot wind of the desert upon the throat and nose leads the camel instinctively to bury its nose in the sand until the fury of the tempest is past.

Besides the meteorological relations which condition the geographical distribution of these affections, there are others which pertain to the *geological character of the soil*, to the *configuration of the locality*, and to the *emanations which arise from the surface of the earth.* The two former furnish additional proof in favor of the power of climatic conditions in the evolution of naso-pharyngeal inflammation. It is not within the scope of the present paper to enter into an elaborate discussion of this vast and imperfectly understood question, but it may be said, in general, that the temperature of a given locality will depend, to a certain extent, upon the color of the soil and the presence or absence of vegetation. In some countries—as, for example, in Savoy—the peasants spread dark earth upon the land which they desire to cultivate early, which causes the snow to melt fifteen to twenty days earlier than in other localities (Tortual); it is a well-known fact that the temperature is lowered and humidity of the soil encouraged by the presence of forests or large tracts of dense undergrowth. The presence of vegetation exerts, too, a remarkable influence upon the chemical composition of the air, and hence upon the development or dissipation of nasal and other forms of catarrh. The noxious exhalations from certain forms of vegetable life probably act as indirect or predisposing agencies in the spread of catarrhal disease, while the presence of others, by purifying and tempering the atmosphere or filling it with certain odors, seems to secure immunity from the affection. The sulphurous air of volcanic regions has been utilized from time immemorial in the treatment of laryngeal affections, and the singular infrequency with which the latter are encountered in places where the air is laden with resinous and balsamic odors has been familiar from the earliest times. The *configuration* of a country enters as a factor in the localization of catarrh in so far as it conduces to exposure to the variations in temperature which have been mentioned above.

There are also a vast number of injurious influences dependent upon *modes of life, dress, imperfect sanitary conditions*, etc., which have been brought forward as the alleged causes of localization of catarrhal affections of the respiratory tract, which, although exercising an undoubted irritating effect, are nevertheless purely secondary and accidental, and have led to crude hypothesis and hasty generalization concerning the essential causes of these diseases.

There are a multitude of conditions which follow as the natural results of imperfect sanitation and professional occupation which act as predisposing and often exciting causes of nasal inflammation. In general, it may be said that residence or work in a confined or overheated atmosphere, or in one filled with impure gases or floating particles of organic or metallic matter, conduces to the development of the disease. Thus it is well known that artisans who are subjected to a dusty atmosphere—tobacconists, workers in woolen goods, stone-cutters, millers, laborers in chemical works, etc., or in overheated apartments, as, for example, bakers—are thereby rendered more susceptible to catarrhal affections. In addition to the meteorological conditions which prevail in elevated regions, as, for example, the Alps, the finely divided particles of metallic dust suspended in the atmosphere are said to be important factors in determining affections of the respiratory apparatus. The nasal erectile bodies are peculiarly sensitive to the impression produced by certain noxious gases, especially those given off in the combustion of coal, while the furnace heat of the modern dwelling, and the dry, impure air of apartments fed by the majority of coal-burning stoves, and the varying temperatures of the different rooms, create a vulnerability of the mucous membrane which, in our American cities, constitutes a not unimportant ætiological factor.

In some parts of our country there is a widespread popular belief that *dust* is the chief factor in the localization of inflammatory disease in the naso-pharynx. As there are some who ascribe all diseases to the peripatetic excursions of a vagrant micrococcus, so there are others who see in dust the source of all our ills. While it is undoubtedly true that dust, when accidentally lodged in the naso-pharynx, may give rise to inflammation, I believe that comparatively few cases originate in that way. In some of the Western States the prevalence of large quantities of dust in the atmosphere is supposed to determine the geographical distribution of the complaint; but even here, in estimating the amount of injury done by dust in this case, we should not forget the important meteorological changes that condition its presence in the atmosphere, nor should we lose sight of the fact that these localities are thousands of feet above the water-level, a condition that subjects them more easily to impressions made by sudden variations in the temperature and brings them directly under the dominion of the winds that sweep across the continent from sea to sea. Moreover when an individual is exposed to an atmosphere filled with dust, the greater portion of the inhaled particles is retained within the nostrils. This is due in a great measure, as I have pointed out elsewhere, to the erection of the turbinated corpora cavernosa, which latter serve, in that respect, a certain teleological purpose. That portion which finds its

way into the posterior nares is carried into the lower (not the upper) pharynx, not only by the force of the inspiratory stream but also in obedience to the law of gravitation. When the atmosphere is unusually dense, as in storms of dust, this erection of the corpora cavernosa is often so considerable as to necessitate mouth-breathing, and it is to a large extent in this way that the lower pharynx and larynx become filled with foreign matter. It is also a notorious fact that in the nasal passages themselves the region of olfaction is much less liable to catarrhal inflammation than the respiratory passage. The nasal pharynx is therefore infinitely less liable to inflammation from a dusty atmosphere than either the larynx or lower pharyngeal cavities.

*Among the influences which, approaching from the external world, encourage the eruption of naso-laryngeal affections, the chief, and at the same time predisposing, exciting cause, and that which determines the geographical distribution of nasal, naso-pharyngeal, and laryngeal catarrh, is that combination of varying meteorological conditions which are understood when speaking of a changeable climate; the home of naso-laryngeal catarrh is the land of the greatest and most rapid thermo- and barometrical change.**

Turning now from the effect of temperature changes and the direct action of local irritation from substances derived from the external world to the agencies which, operating within the organism, determine the localization of catarrhal disease in the nasal passages and throat, we must confess that the ancients exhibited the greatest shrewdness of observation when they referred these affections to defective digestive processes and lowered powers of assimilation. Catarrhal diseases, according to the fathers of medicine, are due to imperfect "coction"—that is to say, imperfect assimilation—and the resulting discharge or secretion was looked upon as aliment which had not undergone the necessary digestive changes, or, in other words, as half-cooked food. While their notions of the ætiology of catarrhal affections were in the main crude and curiously influenced by the prevailing philosophical vagaries of their time, they nevertheless contain an amount of common sense which it behooves us to pause and consider.

It may be said, in general, that all those influences which impair the general health, interfere with the proper circulation or impair the constituents of the blood, retard the processes of digestion and assimilation of food, or beget a hypersensitive condition of the vaso-motor nervous system, react upon the upper respiratory tract in common with the other organs of the economy, and predispose, other things being equal, to catarrhal inflammation of the same. Thus the latter is more liable to develop in anæmic persons with weak, relaxed conditions of the tissues and who lead sedentary lives, and in those of highly nervous organization, than in those of strong and vigorous constitution and who pass most of their time in active out-door exercise. The existence of syphilis or tuberculosis in an individual is a constant invitation to catarrhal inflammations of the nose and throat, and the same is true in regard to the rheumatic, gouty, scorbutic diatheses, to chronic alcoholismus, and a host of other affections.

Over-indulgence of the appetites, excesses of all kinds, habitual interference with the bodily excretions, notably the intestinal, predispose to inflammatory disease of the naso-laryngeal tract, so that Schneider was not far from the truth when he said that the cure of catarrhs consisted in "sobriety, continuous bodily exertion, and tranquillity of mind."

(*To be concluded.*)

* The alternate subjection of the pharynx and larynx to extremes of heat and cold in the ingesta acts, though to a far less degree, in the same manner in determining catarrhal inflammation as the sudden changes in the temperature of the external air.

CATARRHAL AFFECTIONS OF THE NASAL PASSAGES

AS A CAUSE OF

PULMONARY PHTHISIS,

WITH SPECIAL REFERENCE TO THE QUESTION OF HEREDITY.

By WILLIAM CHAPMAN JARVIS, M. D.

(*Concluded from page 265.*)

I will now direct your attention to the color of the mucous membrane of the upper air-passages as an indication of incipient or developed pulmonary phthisis. The color I refer to is a peculiar anæmic, pink hue, resembling that sometimes observed in hypertrophy of the tonsils. This pallor is by no means confined to the atrophic form of rhinitis, where, as far as the nostril is concerned, it invariably occurs, but exactly opposite to what we might expect is discoverable in rhinitis hypertrophica, where its presence should naturally lead one to suspect and find the anæmia of pulmonary phthisis. In two of the reported cases appended to this paper the condition was found in connection with a rhinitis hypertrophica; and in another, likewise phthisically inclined, it was associated with an hypertrophic and atrophic process in the same individual. I still favor the view advanced by me several years since, in an article on laryngeal phthisis,* that anæmia of the upper respiratory mucous membranes influences the character of reparative changes, as exhibited, for instance, in the conversion of accidental abrasions in the larynx into phthisical ulcerations. It would seem to indicate diminished vitality or a lowered power of resistance. As an example, I might mention that my experience in operations upon the septum leads me to expect an exceedingly slow reparative process, and one usually requiring assistance in patients presenting marked anæmia of the septal mucous membrane.

In this class of cases, as we might naturally expect, the slight vascularity of the mucous membrane favors the action of the cocaine salts, and they are, in my experience, the only ones in which we can positively promise freedom from pain before operating.

I have selected a few histories from my case-book as good illustrations of the ætiological relations of nasal catarrh to pulmonary phthisis.

Case I.—Mr. ——, engineer, aged thirty, came to me for treatment in October, 1884. His complaint was a long-

* "Archives of Laryngology," vol. iv, p. 187.

standing catarrh. The right nostril (Fig. 9) for respiratory purposes was practically useless, and had been so as far back as he could remember. Nasal respiration was, and had always been, carried on through the left nostril. Despite, however, the ease with which air was inspired through the free nostril, he had never been comfortable, on account of the respiratory obstruction referred to the narrow nostril, and eagerly utilized the smallest amount of space afforded at intervals by the temporary subsidence of the congested turbinated tissues. In addition to the respiratory discomfort, he was annoyed by the accumulation of inspissated mucus in the larger naris, and was wearied by the constant though ineffectual efforts employed to remove the ropy muco-purulent matter and offensive crusts. He was also tormented with the usual throat and laryngeal symptoms which occur as a result of the disturbances to nasal respiration and drainage. The slightest exposure was likely to be followed by obliteration of the insignificant respiratory aperture in the right naris, producing a disagreeable sense of tension in that nostril, evidently arising from the turbinated turgescence. The same exposure sometimes resulted in attacks of lung trouble, occasionally confining him to the house. In appearance he was thin and anæmic, his emaciation carrying with it more the impression of a peculiar build than an unusual or rapid loss of flesh. His appetite, though usually excellent, was capricious, and even at its best was not followed by any noticeable increase in weight.

Examination.—An examination of the nares anteriorly with my nasal speculum revealed the presence of just those conditions which would serve to account for the symptoms complained of. The vomer, ethmoid, and triangular cartilage projected to the right in the form of a *general* and easy incline from above downward. Anteriorly, however, the columna was displaced laterally to the right as an irregular knuckle of cartilage (see Fig. 9). No evidence of disfigurement of the external naris could be observed on ordinary inspection (another indication of the hereditary character of the complaint). An interesting feature observed upon the septum in the left nostril was a vertical elevation near the ethmo-vomerine suture, caused by the abrupt interruption of the perpendicular plate of the septum at this point. Behind this vertical ridge quantities of glairy or inspissated mucus would collect, and, by reason of the excessive breadth of the inner naris at this point, they would effectually elude the action of the respiratory pressure exerted by the patient to remove them. The turbinated structures and peri-turbinated mucous membrane was markedly atrophic in the larger or left nostril, but the inferior turbinated tissue in the right or narrow nostril was slightly hypertrophied. Just here we note an instructive example of cause and effect, for, as we might have expected, the life-long inspiration of air through a single nostril—unable, through secretory disturbances, to furnish the necessary amount of moisture—is naturally followed by desiccation and atrophy of the pituitary membrane. The right nostril, on the contrary, being almost completely stenosed, is always bathed in the nasal fluids. In other words, with certain modifications, it is a case of unequal distribution of respiratory labor with the natural consequence, a rhinitis atrophica and hypertrophica occurring in the same individual. The pharynx, larynx, and trachea presented the anæmia of phthisis. The patient's lungs were carefully examined by Dr. W. H. Katzenbach, of the Chest Department of Bellevue Hospital, and myself, and our suspicion was confirmed by the detection of the very early signs of pulmonary phthisis.

An interesting point in the patient's family history related to his brother, a physician, who, several years since, was threatened with a pulmonary phthisis and only escaped with his life by abandoning his labors and by careful treatment and systematic change of climate. It is easy to foresee the probable fate of the subject of this history under unfavorable circumstances, for there is every reason to believe that we have here an individual afflicted from childhood with a nasal disease due to a malformed septum, doubtless hereditary in character. I infer the hereditary character of the complaint from the peculiar form of the deviated septum already pointed out, from the fact that the brother and several ancestors of the patient were afflicted with pulmonary phthisis, and for other reasons already given.

Treatment.—Measures were at once employed to relieve the patient of the discomfort occasioned by the accumulation of muco-purulent matter and crusts in the ample interior of the right nostril. This was readily accomplished by thoroughly cleansing the nostril with warm detergent washes, and by the assiduous employment of the cotton probe. The naris, once renovated and relieved of all offending substances, was kept constantly clean by the daily employment of a convenient post-nasal douche, in the use of which the patient acquired much manual dexterity.

To prevent the adherence of nasal crusts to the sinuosities of the nostrils, the membrane was bathed at convenient intervals in a fine spray of vaseline. The douche became part of the patient's daily toilet, and he soon ceased to feel any discomfort except in the right nostril. A sense of oppression from his inability to breathe through this side increased his desire to obtain any relief offered by a surgical remedial measure. I therefore operated with this intent, leveling the deviated structure. This included a portion of the vomer as well as the deflected triangular cartilage. I employed my tubular forceps, fenestrated cartilage forceps, and rongeur or bone forceps. There were two sittings of about an hour each. The use of cocaine upon the patient was particularly satisfactory. A ten-per-cent. solution was applied in the form of a spray, and the parts in two or three minutes were so completely benumbed that bone and cartilage were crushed at short intervals without the slightest manifestation of pain. I have noticed a singular obtuseness to pain in other cases in which cocaine has been applied to an anæmic mucous membrane.

Fig. 9, taken from a life-sketch, shows the deviated septum anteriorly, and Fig. 10 the same after operating. Nasal respiration was completely re-established through the stenosed nostril, and this and the relief from other catarrhal complications left the patient in a most excellent condition —almost, in fact, unconscious of his trouble.

He embraced a good opportunity, and is now traveling abroad; on his return he will arrange to spend the winter

farther south than New York. Under the favorable conditions afforded by physical ease and a suitable climate the chances of this individual escaping the ravages of tubercular phthisis appear most excellent.

Fig. 10.

Case II.—Mr. ——, merchant, aged thirty-one, from Owego, N. Y., consulted me in January, 1884. The patient distinctly recollects having suffered with a nasal catarrh seven years ago. Although the affection at that time proved troublesome, still the excellent state of his general health induced him to consider the malady as trifling and transient in character. Small quantities of phlegm were constantly hawked up from behind the palate. There was a disposition to clear the windpipe of particles of viscid matter. At that time and for several years subsequently he plowed the fields as a farmer.

The catarrhal symptoms, instead of disappearing, as he had hoped and expected, became more pronounced and troublesome, and, his stomach becoming incidentally involved, dyspepsia was added to his misery. The prolonged physical and mental discomfort resulting from the persistent catarrhal disturbances ultimately sapped his energy and strength, rendering him unfit to pursue his usual occupations.

Clammy night-sweats commenced last summer, and have continued with varying frequency and severity since then. Becoming alarmed about himself, he was easily induced to seek medical advice.

Prominent among the symptoms given me at the first interview was a cough, which had, however, commenced only about a year ago. Phlegm was expectorated with the cough, particularly on rising in the morning. The cough, though annoying, was not painful. Six months ago only a pellicle of mucus was raised in coughing. There is now a disposition to draw flakes of mucus from behind the soft palate.

Examination.—General thickening of the nasal mucous membrane, post-inferior turbinated hypertrophy (dextra). The usual inflammatory redness of chronic hypertrophic coryza is replaced by the pale, anæmic hue peculiar to atrophic catarrh. The same pallor occurs upon the mucous membrane of the throat, larynx, and trachea. A livid, circumscribed, inflammatory process is visible upon the edge of the left true vocal cord.

Percussion furnished pronounced dullness over a large extent of the chest. The resonance on the right side was higher pitched than on the left. Auscultation demonstrated the presence of numerous fine crepitant râles diffused throughout the right lung and commencing in the left; also cog-wheel respiration, etc.

The patient, though feeble, was able to exercise in the open air and to visit my office. This, however, was in accordance with his own wish. Indeed, he seemed to dread nothing so much as confinement to the house—a natural feeling for one who has largely led an out-of-door life. The unusually cold and inclement February weather severely tried the patient's feeble powers of endurance, and with the decrease in his appetite and strength there was an increase in the copiousness and frequency of the night-sweats. I foresaw the patient's rapid decline under these unfavorable surroundings. He followed my advice and went South to escape the harsh wintry weather, and possibly to prolong his life a little. On the advent of the warm weather he returned, passing through New York on his way home. I then examined his chest and found that the fine râles had become generally diffused throughout both lungs. The patient safely reached home and died, near the middle of the summer, surrounded by his family.
